The percutaneous absorption of drugs is important from three perspectives. Veterinary clinicians should be concerned about how much of a drug actually penetrates the skin to achieve a pharmacological effect in treating diseases of the skin. This can be a function of several factors including vehicle selection, hydration state of the stratum corneum, partition coefficient of the drug from vehicle into the stratum corneum lipids, the integrity of the stratum corneum, and cutaneous blood flow. The same endpoints, but in an opposite direction, also impact the efficacy and duration of effect for topical transdermal products. The final need for knowing the extent of percutaneous absorption lies in the field of public health and food consumption. Many compounds used in food animals are applied to and absorbed through the skin and enter the systemic circulation. Many of these compounds are stored in edible tissues (fat, muscle) for long periods of time, causing concern about residues in these tissues (Baynes et al., 1997; Riviere, 1992).

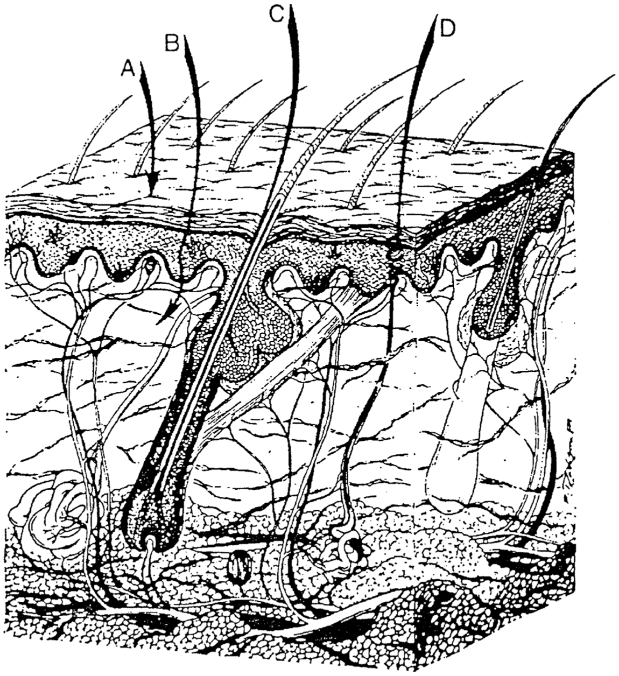

Figure 47.2 A schematic view of the skin and the four routes of drug penetration. Drugs can penetrate through the stratum corneocytes (A), between the stratum corneocytes (B), transfollicularly via any hair follicle (C), or via an eccrine sweat gland or sebaceous gland (D).

The stratum corneum is accepted to be the major barrier, but not the only barrier, to percutaneous penetration in most species of animals. Passive diffusion is defined here as the movement of matter from one space to another space by random molecular motion. No known active transport processes are used by stratum corneum to modulate percutaneous absorption. To better understand how substances diffuse through the stratum corneum, it is convenient to think of the stratum corneum as a wall in a "brick and mortar" configuration (Elias, 1983), with the bricks representing the stratum corneocytes and the mortar representing the lipid matrix around them, as shown in Figure 47.3. In this context, permeation through the stratum corneum might occur via two routes. The first involves the drug traversing through the stratum corneocytes ("bricks") and extracellular lipid matrix ("mortar"), through the cells of the deeper epidermal cells, and then into the systemic circulation. The second route involves the chemical maneuvering its way through the stratum corneum via the intercellular lipid matrix only. It is generally accepted that the primary route of penetration is via the intercellular pathway. Because of the structure of the stratum corneum and the metabolic capabilities of the lower epidermal cells, the veterinarian must be aware that only a small percentage of the drug that is topically applied is going to actually penetrate the stratum corneum. This small fraction of the total dose will need to be able to affect the disease process occurring in the underlying layers of the epidermis.

The molecular structure of the intercellular lipid matrix throughout the epidermis is in a liquid crystalline configuration, consisting of fatty acids, ceramides, triglycerides, sterols, sterol esters, cholesterol sulfate, and miscellaneous alkanes. As epidermal cells migrate superficially and transform into the cells of the stratum corneum, the lipid content surrounding these cells changes from polar to more neutral in nature. Specifically, phospholipids and triglycerides tend to decrease while fatty acids, cholesterol, cholesterol sulfate, ceramides, and sphingolipids increase as the epidermal cells differentiate (Elias, 1992). Enzymes are also present within this matrix of lipid. These lipids organize themselves into a lipid bilayer structure, with the hydrophobic ends of the molecules orienting themselves with other hydrophobic ends, and the hydrophilic ends orienting themselves in a similar fashion. More than one lipid bilayer can be formed within the intercellular matrix, leading to the formation of hydrophilic and hydrophobic channels, as illustrated in Figure 47.4. One might assume that this complex lipid barrier would result in very low absorption profiles for hydrophilic (water soluble) compounds since these molecules would

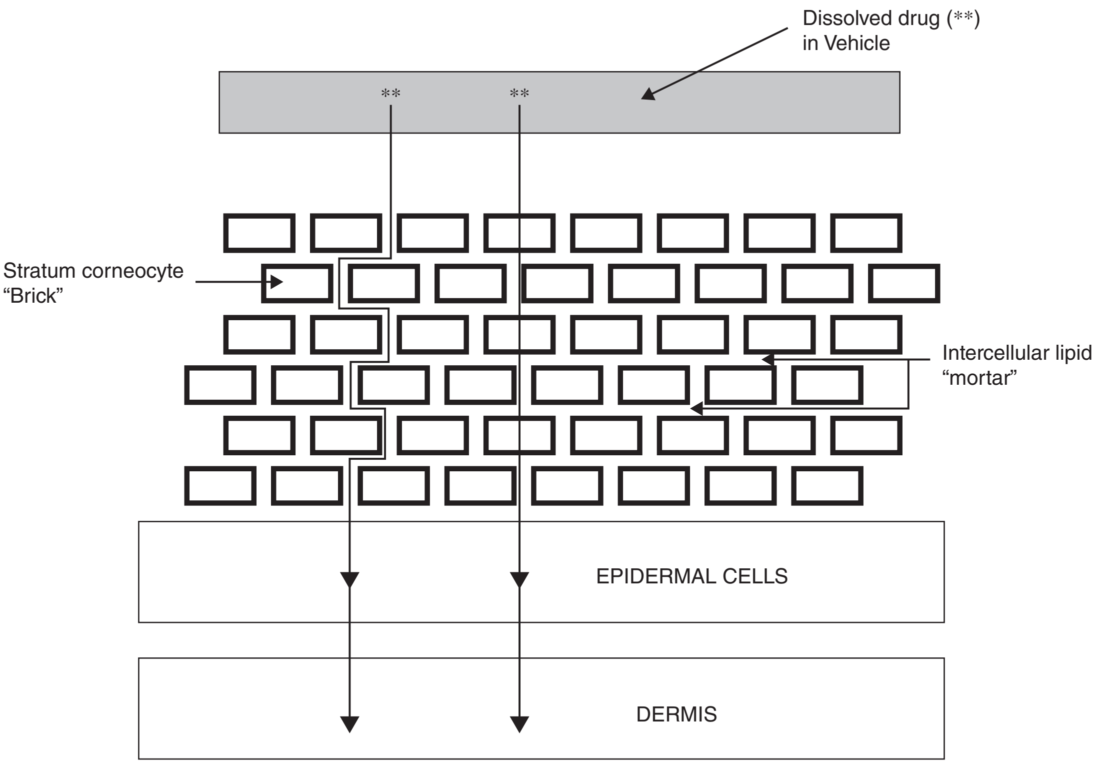

Figure 47.3 Simplistic "brick and mortar" model of the skin. Drugs can penetrate by traveling around the stratum corneocytes through the lipid matrix, or drugs can pass through each corneocyte via the lipid matrix.

have difficulty crossing a hydrophobic barrier, but some studies have shown that many hydrophilic compounds penetrate the epidermis in much higher quantities than predicted, implying that there are other mechanisms whereby hydrophilic compounds permeate the stratum corneum. The primary mechanism by which this is accomplished is for hydrophilic molecules to penetrate through fluctuations, or "kinks," in the lipid alkyl chains (Potts and Francoeur, 1992; Potts et al., 1992). Further, the permeation of hydrophilic molecules (such as water,

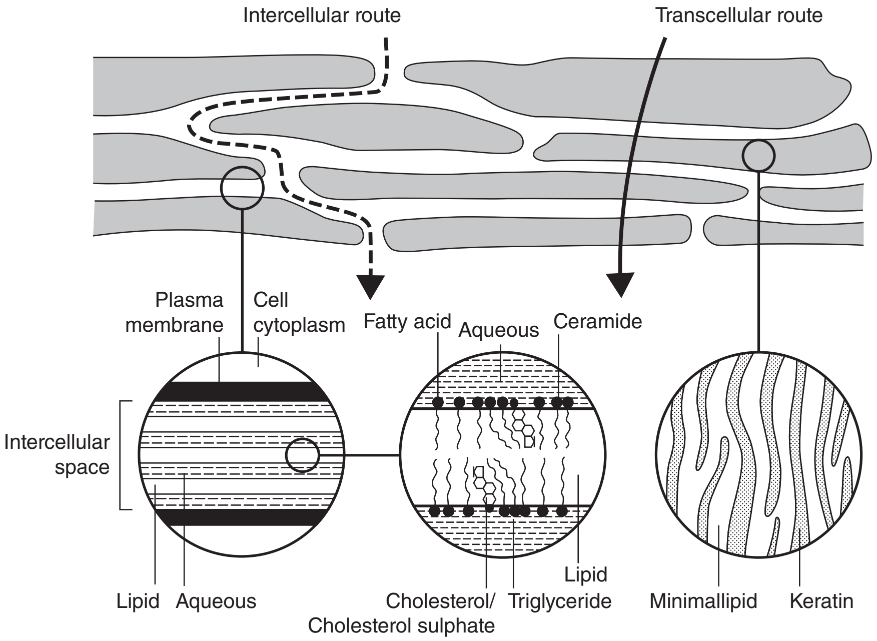

Figure 47.4 The lipid bilayer model of the stratum corneum.

methanol, ethanol, etc.) through the lipid matrix is due to their small size and molecular weight, which aid them in traveling through the lipid matrix via passages established by the lipid alkyl chains. This view is supported by the observation that larger hydrophilic molecules have lower percutaneous absorptions than their smaller molecular weight counterparts. Alternatively, penetration may also occur through the aqueous channels formed between the polar head groups of the lipid layers.

More recently, the role of tight junction in the barrier function of the skin and permeability to substances has been discovered. Tight junctions are present in the SG and are composed of a number of proteins that selectively and dynamically regulate the penetration of substances through epithelia, including the epidermis. Tight junctions are actively remodeled to allow the migration of keratinocytes toward the surface without compromising the barrier function of the skin (Matsui and Amagai, 2015).

Chemicals may also permeate the skin using the skin appendageal route, mostly by way of hair follicles and sweat ducts. The importance of the transappendageal route on percutaneous absorption is controversial, but some studies indicate that the importance of this route tends to be species specific (Pitman and Rostas, 1981). Generally, those animals possessing a sparse number of hair follicles per area of skin (humans, pigs) are considered to have little, if any, absorption of topically applied compounds via this route when compared to those animals having a high density of hair follicles (cattle, sheep). In these latter animals, the stratum corneum barrier is just as impermeable to drugs as that of their less-haired counterparts, but the drug permeates the skin barrier via the hair follicles, sweat ducts, or other openings in the stratum corneum, increasing the percutaneous absorption of the chemical. It has been demonstrated that transappendageal absorption is high initially, then becomes insignificant, due to the small surface area of follicles and glands in relation to the total surface area of the stratum corneum. Topical delivery of pesticides to domestic livestock has been used for many years for the control of external as well as internal parasites of these animals, indicating that enough of the pesticide is absorbed systemically to kill some internal parasites while not harming the host animal (Riviere, 1992).

Two events must occur for a drug to be successfully delivered to the epidermis under the stratum corneum: (i) the drug must diffuse out of the vehicle and onto the surface of the stratum corneum; and (ii) the drug must be able to penetrate the stratum corneum (Idson, 1983). Restated, the vehicle in which the topical drug is being delivered should have significantly less affinity for that drug than for the stratum corneum. In actuality, many factors enter into the release of drug from the vehicle and its penetration through the stratum corneum. These factors have been mathematically described for steady-state kinetics in Fick's first law of diffusion (Idson, 1983):

$$dQ/dt = (PC)C_vDA/h$$

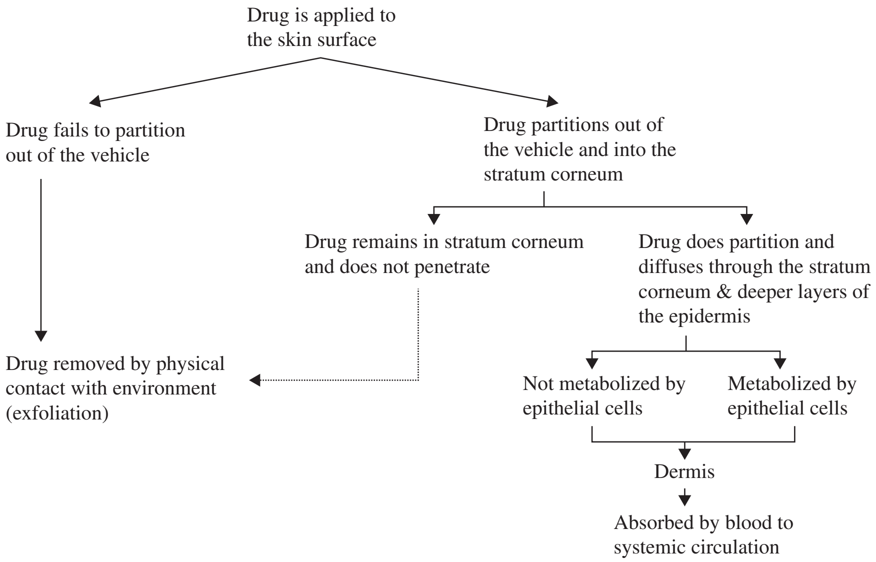
where dQ/dt is a steady rate of penetration, PC is the drug's partition coefficient between the vehicle and the stratum corneum, C_v is the concentration of the drug dissolved in the vehicle, D is the diffusion coefficient, A is the area of skin to which the drug is applied, and h is the diffusion path length through the stratum corneum. In short, Fick's law states that the driving force causing the transfer of a drug from regions of high concentration to areas of low concentration is proportional to the concentration gradient (Idsen, 1975). The diffusion coefficient is primarily correlated to the partition coefficient of the penetrant, and can also be predicted from a knowledge of the drug's molecular volume and hydrogen bond activity (Potts and Guy, 1995).

Only the nonionized moiety of a weak acid or base is available for diffusion across the stratum corneum. The pH of skin is variable and sensitive to hydration state. The typical pH of skin ranges from 4.2 to 7.3. For drugs with pK_a values within this range, the ionized fraction may vary according to the principles governed by the Hendersen–Hasselbalch equation, which would alter the amount of drug available for absorption. This is usually controlled for in the dermatological formulation by use of buffering systems. Theoretically, vehicles with different pH may have species-specific absorption for drugs with pKa values in this range.

Topical Vehicles

A vehicle is defined as the medium in which a medicinally active agent is topically administered. It is a gross misconception that the vehicle in which topical drugs are dissolved is inert and has little effect on the skin; in fact, the physical and chemical properties of the vehicle will largely determine how successfully the drug will penetrate the skin. This has been clearly demonstrated with the pesticide carbaryl in pigs (Baynes and Riviere, 1998). The vehicle may penetrate the stratum corneum to some extent and change the solubility of the intercellular lipid matrix. A simplistic view of the fate of topically applied drugs has been outlined in Figure 47.5.

The partition coefficient is a unitless measure of the relative affinity of a compound between a highly hydrophobic phase (usually octanol) and a hydrophilic phase (water), and is a physicochemical factor that has a major role in determining the percutaneous absorption of a chemical. As the partition coefficient increases, the compound has a greater affinity for the lipid phase and less affinity for the water phase. As discussed earlier, the



Drug is applied to the skin surface
Drug fails to partition out of the vehicle
Drug partitions out of the vehicle and into the stratum corneum
Drug remains in stratum corneum and does not penetrate
Drug does partition and diffuses through the stratum corneum & deeper layers of the epidermis
Drug removed by physical contact with environment (exfoliation)
Not metabolized by epithelial cells
Metabolized by epithelial cells
Dermis
Absorbed by blood to systemic circulation

Figure 47.5 Schematic representation of the fate of topically applied drugs.

intercellular matrix of the skin consists of several different types of lipid, the ratios of which may vary from site to site, and furthermore be modulated by vehicle penetrating the skin.

Skin penetration of many chemicals has often been correlated to the partition coefficient of the penetrant. Generally, as the log of the partition coefficient increases, lipid solubility increases and there is an overall increase in the percutaneous absorption of the compound through the skin. This scenario is not always the case, however; some poorly lipid soluble compounds (i.e., low partition coefficients) sometimes penetrate the skin much more easily than compounds with higher partition coefficients. Once penetration into the skin occurs, the molecule must eventually leave the lipid phase to be able to reach the systemic circulation. Compounds with high partition coefficients tend to remain within the lipid of the skin and form a reservoir rather than pass through; this is a well-documented phenomenon in skin (Muhammad et al., 2005). It has been shown that a log partition coefficient of 1–4 is desirable for skin penetration of most compounds.

Absorption of the vehicle into the stratum corneum is another factor to consider, since the vehicle may cause some disruptions in the composition and orientation of the intercellular lipid matrix. Partition coefficients for use in predicting the percutaneous absorption of topically applied drugs should ideally measure the index of affinity of a drug between the vehicle the drug is being delivered in and the lipid/vehicle composition of the stratum corneum. Unfortunately, few measurements of this kind are in existence because interaction of the vehicle with the stratum corneum lipids invalidates its determination. The role of partition coefficients in skin has been extensively reviewed elsewhere (Surber et al., 1990a, 1990b; Sloan et al., 1986; Aungst et al., 1990).

The optimal vehicle is one in which the drug is soluble enough to enter into solution, but has less affinity for the vehicle than the stratum corneum lipids, thereby favoring partitioning from the vehicle into the epidermis. Optimal delivery for a polar drug may thus be a relatively hydrophobic vehicle that has sufficient solubility to dissolve the drug. However, if a drug is too soluble in a vehicle relative to the stratum corneum, the drug may persist in the vehicle and only slowly release drug into the skin for as long as the vehicle stays on the skin.

The effect of the vehicle on chemical absorption has been quantitated based on competing physical chemical interactions of the drug and the vehicle versus the skin, using quantitative structure activity relationship principles (Riviere and Brooks, 2005, 2007; Karadzovska et al., 2013a, 2013b; Riviere et al., 2014). These studies also compared topical ectoparasiticides vehicle modulation between canine and porcine skin and has the potential for rationally designing topical drug formulations based on physical chemical principles.

The ability of the vehicle to stay on the skin surface long enough to allow passive absorption of the drug to occur is an important factor in passive drug absorption. The vehicle can be removed by three mechanisms: (i) absorption of the vehicle through the stratum corneum, (ii) evaporation from the skin surface into the surrounding air, or (iii) physical removal (rubbing, licking, scratching, etc.). If the vehicle penetrates the stratum corneum more quickly than the drug, the concentration of the drug in the vehicle left on the surface of the stratum corneum will increase, which would increase the concentration of drug driving absorption, but would also have the potential of inducing precipitation of the drug onto the skin's surface. The vehicle may also change the permeability of the lipid matrix (e.g., function as an enhancer). Evaporation of the vehicle will result in a similar scenario.

Vehicles may also affect the hydration state of the stratum corneum, which in turn may affect the rate at which topically applied compounds can penetrate the stratum corneum. Occlusion of the skin significantly increases the penetration of parathion (Chang and Riviere, 1993) and other compounds. The vehicle can accomplish this by modulating insensible cutaneous water loss or skin transpiration. "Transpiration" is the term used to describe the passage of water vapor from the body, through the epidermis, and out to the surrounding environment. The act of transpiration is an important factor in determining percutaneous absorption of chemicals. In the normal state, the epidermal cells below the stratum corneum are highly hydrated compared to the stratum corneum. The water in and around these epidermal cells tends to slowly "percolate" upward, following the decreasing concentration gradient of water toward the less hydrated stratum corneum, eventually passing through the stratum corneum and into the environment. This phenomenon can be noninvasively assessed by measuring transepidermal water loss (TEWL) and has been correlated to the stratum corneum permeability of hydrophilic drugs. The stratum corneum normally maintains a 10–20% hydration state. When hydration of the stratum corneum occurs, which may reach 60–80% of the total stratum corneum's mass, this water "opens" the compact substance of the stratum corneum and reduces the density of the intracellular structures, thereby decreasing the cells' resistance to passive diffusion and allowing substances to permeate more readily than in the normal, dehydrated state. Hydration of the stratum corneum can be accomplished by slowing the rate of epidermal water loss to the environment by applying occlusive emollients to the skin (petrolatum, lanolin, etc.), by applying a nonwater-permeable membrane (patch), by soaking the skin in water, or by increasing the relative humidity of the air surrounding the skin (Blank et al., 1984). An increase in percent hydration from 10 to 50% in the stratum corneum can result in as much as a tenfold increase in diffusion constants (Idson, 1983). This effect of environmental humidity and occlusion of the absorption of parathion through pig skin was clearly demonstrated (Chang and Riviere, 1993).

Even when fully hydrated, the stratum corneum is one of the most water-impermeable biological membranes found in nature (Idsen, 1975). Similarly, decreasing the hydration of the stratum corneum can decrease percutaneous absorption of substances. Dehydration of stratum corneum cells below the normal 10–15% usually results in "dry skin" and is a secondary symptom of many dermatological diseases. Decreased stratum corneum hydration often results in a rugged and rough feeling to the skin, along with cracking, increased desquamation of the stratum corneum, and possible secondary septic or aseptic dermatitis. Dry skin can be treated by (i) treating the underlying condition causing the disease and/or (ii) applying agents that will increase the hydration of the stratum corneum by slowing transepidermal water loss. Applying keratolytics (discussed in Section Keratolytics, Keratoplastics, and Antiseborrheics) is also of use.

This discussion should point out that selecting a vehicle that increases the amount of water in the stratum corneum will most likely result in more permeation of drug to the underlying affected tissues, an important factor in successful dermatological therapy. In diseases involving dry skin, returning the stratum corneum to its normal hydration state should also be a goal of dermatological therapy.

In summary, the vehicle, not just the choice of drug, plays a crucial role in determining the success or failure of dermatological therapy. No "ideal vehicle" exists; the veterinary clinician must evaluate the patient's skin lesion and should determine what drug is indicated and which vehicle would best augment that therapy. Both factors may markedly influence the success of therapy. Pharmaceutical classifications of topical vehicles are covered in Section Classification Of Dermatological Vehicles.

Other Factors Affecting Percutaneous Absorption

Other factors that may enhance or hinder percutaneous absorption are the molecular weight of the chemical, temperature, blood flow, and skin age. Increasing the blood flow through the dermis would suggest a more rapid removal of drugs absorbed from the epidermis (Riviere and Williams, 1992). Vasoconstriction of these vessels has been shown to significantly decrease percutaneous absorption of 6-methylprednisolone and testosterone (Malkinson, 1958). The temperature of the air surrounding the skin plays a role in blood flow, with warmer environmental temperatures or skin showing one of the cardinal signs of inflammation (heat) increasing the blood flow to the skin and cooler temperatures decreasing cutaneous blood flow. An inverse relationship appears to exist between absorption rate and the molecular weight of the drug (Idsen, 1975). Although smaller molecules tend to increase total topical dose absorbed through the skin, there is considerable variability in the amounts percutaneously absorbed among compounds of similar molecular weights (Idsen, 1975; Tregear, 1966).

It is important to note that skin barrier function is impaired in inflamed skin and in certain conditions such as atopic dermatitis. Thus application of topical products in patients with inflamed or traumatized skin is increased leading to potentially increased risk for adverse effects.

Penetration Enhancers

The stratum corneum has been portrayed as a formidable and almost impenetrable barrier to the absorption of lipophilic, hydrophilic, and amphoteric xenobiotics. Many efforts have been made to adjust the barrier of the stratum corneum to increase the percutaneous absorption of topically applied xenobiotics, for the most part with only limited success. The barrier function of the stratum corneum can be structurally modified using a relatively small class of compounds, collectively known as penetration enhancers or penetration accelerants, that increase the percutaneous absorption of many compounds.

Many reports exist in the human and veterinary literature of various agents that have been shown to accelerate penetration of compounds through the skin, but few describe the precise mechanism by which an individual penetration enhancer performs this function. One theory, the lipid–protein partitioning concept, has been proposed for the mechanism of action of all the known penetration enhancers, including penetration via the intercellular as well as the intracellular routes (Barry, 1991). For both routes, this theory acknowledges that polar (hydrophilic) molecules permeate the skin via polar channels (either by aqueous pores or by alkyl group modulation), which are different from the channels used by nonpolar (hydrophobic) molecules. After application to the skin surface, the drug molecules diffuse out of the vehicle and into the stratum corneum and begin to traverse the many aqueous and lipid barriers found in the intercellular matrix (see Figure 47.4) in order to reach the rest of the body via the systemic circulatory system. Penetration enhancers are hypothesized to modify these lipid and aqueous bilayers of the intercellular lipid matrix and allow topically applied compounds to penetrate the stratum corneum more readily by disrupting the normally very organized structure of the lipid layers.

It is convenient to organize the known penetration enhancers into four common subgroups: azone and its derivatives, urea and its derivatives (1-dodecylurea, 1,3 didodecylurea, 1,3 diphenyl urea, propylene glycol, dimethylisosorbide), the terpenes (carvone, pulegone, piperitone, menthone, cyclohenene oxide, terpinen-4-ol, and others), and the aprotic solvents (dimethylsulfoxide, demethyl formamide, decylmethyl sulfoxide, 2-pyrrolidone, and others). At the present time, the first three groups are used almost exclusively in human pharmaceutical products and research and will not be discussed here. The most extensively used penetration enhancer in veterinary medicine, primarily for transdermal applications, is dimethylsulfoxide (DMSO).

DMSO is a product from the processing of wood pulp and is a dipolar and aprotic solvent. DMSO is also produced by phytoplankton and is present in many foods (Herschler, 1982). DMSO has been used to treat a myriad of skin ailments, including otitis externa, interdigital cysts, lick granulomas, superficial burns, skin grafts, and snakebites; and to reduce the engorgement of the mammary glands of the nursing bitch (Knowles, 1982). Other less common veterinary uses for DMSO have also been described (Jacob et al., 1965; Jacob, 1982; Knowles, 1982). In addition to penetration enhancement, DMSO is also bacteriostatic, vasodilatory, fibrinolytic, antiinflammatory, and produces some degree of topical analgesia. DMSO produces a thermal effect after direct application to the skin, which may function to alleviate pain in the skin and in the underlying muscle and bone. The transient erythema that is induced after topical administration of DMSO is due to the release of histamine (Jacob et al., 1965). These effects are considered transient and reversible and will not generally increase in severity after multiple treatments, indicating no need to discontinue therapy. Potential skin irritation occurs at concentrations of greater than 70% (see previous editions of this text for more information on DMSO).

DMSO has the potential to enhance the percutaneous absorption of a number of topically applied compounds. The exact mechanism of this percutaneous absorption enhancement has not been clearly elucidated. DMSO appears to produce only minor morphological changes in the skin. Penetration enhancement of topically applied chemicals dissolved in DMSO does not appear significant until the DMSO concentrations approach 50–60%, with overall permeability of the compound tending to increase as the concentration of DMSO applied to the skin approaches 100% (Kurihara-Bergstrom et al., 1987). Many mechanisms have been proposed to attempt to explain why DMSO enhances the percutaneous absorption of such a wide variety of compounds. Possible mechanisms include elution of stratum corneum lipids and delamination of the horny layer by stress resulting from crosscurrents of highly water-interactive DMSO and water (Kurihara-Bergstrom et al., 1986). Sharata and Burnette (1988) determined that in nude mice skin, DMSO transformed the highly compact cell contents of the basal stratum corneum (keratin) into a looser meshwork of filamentous bundles, resulting in much more porous intracellular structure with an increase in intracellular surface areas, which they believed might increase percutaneous transport. Whatever the mechanism, DMSO has been shown to enhance the percutaneous absorption of many compounds, including water, hydrocortisone, salicylic acid, tubocurarine HCl, multiple glucocorticosteroids and antibiotics, estradiol, hexachlorophene, phenylbutazone, and a host of other topically applied chemicals.

Finally, recall that there is no universal penetration enhancer or vehicle, for example pluronic lecithin organogel (PLO) gel, that would be optimal for the delivery of all classes of topical drugs across the skin of all species. Carefully controlled studies have begun to show lack of transdermal delivery of several drugs via this approach (Hoffman et al., 2002; Mealey et al., 2004; Miller et al., 2014), though application of methimazole in PLO gel on the permeable inner pinnae of cats was as effective as oral dosing (Hill et al., 2011; Boretti et al., 2013). Many pour-on ectoparasiticides contain, as one formulation component, the glycol ether transcutol (diethylene glycol monoethyl ether) as a solubilizing agent in ethanolic vehicles. Selection of an optimal vehicle for transdermal delivery of a drug requires a close match between the physical chemical properties of the drug, vehicle, and skin lipids.

Electrically Assisted Transdermal Drug Delivery

An alternative approach to overcome the stratum corneum permeability barrier is by using electrical (iontophoresis) or ultrasonic (phonophoresis) energy, rather than the concentration gradient of diffusion, to drive drug through the skin (Riviere and Heit, 1997). These techniques hold the most promise for delivering large drugs such as peptides and oligonucleotides that now can be administered only by intravascular injection. With these techniques, dose is based on the application surface area and the amount of energy required to actively deliver drug across the skin. In iontophoresis, this amounts to a dose being expressed in mAmps/cm^2. Formulation factors are also very different, since many of the components used are also delivered by the applied electrical current in direct molar proportion to the active drug. Finally, a related strategy is to employ very short-duration high-voltage electrical pulses (electroporation) to reversibly break down the stratum corneum barrier, allowing larger peptides, and even small proteins, to be delivered systemically (Riviere et al., 1995). These approaches, if applied to veterinary medicine, could have implications for the use of controlled transdermal delivery as a viable method of drug delivery.

Classification of Dermatological Vehicles

As discussed in the introduction to this chapter, the defining difference between dermatological and other treatment areas of veterinary pharmacology is the topical route of administration coupled with the overriding influence that the dosage vehicle exerts on absorption and activity of the applied drug. Classification of vehicles was introduced in Chapter 5. The vehicles used as veterinary dermatologics have been historically classified into seven broad categories (Harvey, 1985; Block, 1985; Rippie, 1985; Swinyard, 1985; Swinyard and Lowenthal, 1985; Nairn, 1985).

Adsorbents and Protectives

Adsorbents and protectives are used extensively in many veterinary pharmaceutical preparations. Adsorbents act by binding gases, toxins, and some organisms (such as bacteria) to prevent exposure to the damaged skin surface. Protectives function by providing an occlusive layer of protection from the external environment or by providing mechanical support to the affected area. Protectives and adsorbents can be further subdivided into two subclasses: dusting powders and mechanical protectives.

Dusting powders are generally inert and innocuous substances. They include starch, calcium carbonate, talc, titanium dioxide, zinc oxide, and boric acid. Many are used in drug formulations alone or as a vehicle for the delivery of other drugs. If the powder particle has a smooth surface, it will act mainly to prevent friction, thus protecting abraded and raw skin surfaces; powder particles with rough or porous surfaces act on the skin by absorbing moisture. Water-absorbing powders tend to coalesce and eventually occlude the skin's surface when wetted and therefore should not be used on wet, moist, or highly exudative skin surfaces. Powders that also contain starch or other carbohydrates that are allowed to cake onto these moist skin surfaces give bacteria and fungi (mainly *Candida* spp.) a source of energy, allowing them to proliferate. This may lead to a secondary bacterial and/or fungal skin infection or exacerbation of an existing microbial skin infection. Powders should not be used within body cavities (thorax, abdomen) or in skin abscesses, especially those powders containing talc. Talc has been shown to promote severe granulomatous reactions when used in these areas but is relatively innocuous when used on intact skin surfaces.

Mechanical protectives provide an occlusive film that protects the underlying skin from irritants present in the external environment (ultraviolet radiation, contact irritants, toxins), provide mechanical support, and are popular vehicles for many drugs. Many members of this subgroup are used to treat cutaneous ulcers and other hard-to-heal cutaneous wounds. Compounds in this group include kaolin, lanolin, anhydrous lanolin, mineral oil, olive oil, peanut oil, petrolatum, zinc stearate, and recently a number of synthetic polymers.

Demulcents

Demulcents are generally high molecular weight compounds that are water-soluble and function by alleviating irritation (*demulcere,* "to smooth"). Like the compounds listed in the protectives group, demulcents can coat the surface of damaged skin and protect the stratum corneum and underlying cellular structure of the epidermis by forming a protective barrier against the surrounding environment. They differ from protectives in that they inherently reduce the irritation from these external stimuli. This group comprises a large and diverse number of chemicals, including mucilages, gums, dextrins, starches, polymeric polyhydric glycols, glycerin, gelatin, hydroxypropyl cellulose, hydroxypropyl methylcellulose, hydroxyethyl cellulose, methyl cellulose, polyvinyl alcohol, and recently silicone-based polymers such as dimethicone. The dried gum extracts from the acacia and tragacanth plants can readily dissolve in water to form mucilages (see previous editions of this text for more detail). The most commonly used demulcents in veterinary dermatology today are glycerin, propylene glycol, and the polyethylene glycols.

Glycerin is a hygroscopic, trihydric alcohol prepared from propylene and has been used for many years as a suppository, with high concentrations of this vehicle relieving constipation by drawing water from the body and into the colon. Glycerin is a clear, colorless liquid that is miscible with water and alcohol and has been used neat to reduce corneal edema and to facilitate ophthalmoscopic examinations. Used in high concentrations topically on the skin, glycerin may dehydrate and irritate the skin, thereby increasing transepidermal water loss. Lower concentrations of glycerin absorbed into the skin hydrate the stratum corneum because of glycerin's hygroscopic nature. Despite its side effects, glycerin makes an excellent vehicle for topical drug delivery when used at lower concentrations.

Propylene glycol (1,2 propanediol) is a hygroscopic, colorless, odorless water-soluble liquid that is miscible with many compounds (water, alcohols, acetone, many volatile oils) and is also bacteriostatic, fungistatic, and nonocclusive. It was first considered for use in 1932 to be used with a drug to treat human syphilis and has also been used as a nontoxic antifreeze in dairies and beer breweries (Catanzaro and Smith, 1991). Propylene glycol is an ideal medium for a formulation component for topical and transdermal delivery of many drugs in animals and humans, as well as for many oral and parenteral drug formulations, such as antitussives and shampoos. Propylene glycol spreads evenly onto the skin's surface and has a very low evaporation rate; it is not greasy to the touch, does not stain clothing or hair, and has some effect on slowing transepidermal water loss, thereby hydrating the stratum corneum to some extent. Topical hypersensitization and other toxicities are frequently seen in clinical practice in patients with predisposition toward allergies. For this reason clinicians need to be aware of potential worsening of disease while using products containing propylene glycol and the need to select alternative formulations. This can be of great importance when selecting topical products for otitis therapy.

Polyethylene glycols are a group of structurally similar compounds that differ in molecular weight. The larger the number, the higher the molecular weight and the more viscous the formulation becomes. At ambient temperature, polyethylene glycols 200, 300, 400, and 600 are clear viscous liquids; polyethylene glycols 900 to 9000 are semihard waxy solids at room temperature. As a group, the polyethylene glycols do not easily hydrolyze and are nontoxic, bland, highly water soluble, and nonvolatile.

Emollients

Emollients are bland, fatty materials often used to soften or moisten the skin. Emollients are particularly useful when treating skin conditions resulting from water-soluble irritants and airborne bacteria because of their ability to act as a protectant, sequestering the damaged skin away from these noxious stimuli. When used topically, emollients soften skin by decreasing transepidermal water loss, or transpiration (discussed in Section Topical Vehicles), and increasing the hydration of the stratum corneum. Therefore, this is a useful group of compounds for treating dermatological conditions involving dry, crusty, or flaky lesions of the epidermis. Emollients are used today as vehicles for many lipid-soluble drugs. Examples of commonly used emollients are listed in Table 47.2.

Astringents

Astringents precipitate protein, toughen the skin, promote healing, and dry the skin when applied topically. When used to coagulate blood, astringents are said to be styptic and elicit a mildly uncomfortable sensation when applied to small open wounds. Most of the chemicals in this group are inorganic salts of aluminum, zinc, potassium, and silver, and include aluminum chloride, aluminum sulfate, calamine (a combination of Fe_2O_3 and ZnO_2), potassium permanganate, silver nitrate, zinc chloride, zinc oxide, zirconium chlorhydrate, and tannic acid. There are many germicidal agents that also have astringent activity. Other astringents are of vegetable origin, most of these preparations owing their activity to tannic acid (gallotannic acid). Astringents in the vegetable-derivative group include gallic acid, kino, krameria, and rubus (blackberry) (see previous editions of this text for more detail). Astringents have limited uses in veterinary medicine today.

Table 47.2 Emollients in use today

Official vegetable oils	Animal fats	Hydrocarbons
Olive oil	Lanolin (wool fat with water added)	Paraffin
Cottonseed oil	Anhydrous wool fat (no water added)	Petrolatum
Corn oil	Lard	White petrolatum (Vasoline)
Almond oil	Whale oil	Mineral oil
Peanut oil		White/yellow waxes (beeswax)
Persic oil		Spermaceti
Cocoa butter		

Rubefacients, Irritants, and Vesicants

Chemicals in this class are used to induce hyperemia (rubefacients), hyperemia and inflammation (irritants), or cutaneous blisters (vesicants). Heat applied to the skin via a hot-water bottle, heat lamp, moist hot pack, or an electric heating pad are acceptable rubefacients and are extensively used in human medicine. Chemical rubefacients are more commonly used in veterinary medicine, mainly due to the difficulty in applying the heat sources listed above for extended lengths of time. An abbreviated list of chemicals that are known rubefacients, irritants, or vesicants includes anthralin, camphor, coal tar, cresote, ichthamnol, menthol, methyl salicylate, resorcinol, cantharidin, black mustard, iodine, mercuric iodide, capsicum, chloroform, alcohols, turpentine, thymol, and pine tar. With the exception of coal tar, most members of the chemical group are not commonly used in modern veterinary practice because of their potential toxicity. Coal tar is a component found in many veterinary dermatology preparations (especially shampoos) and is a by-product of the distillation of bituminous coal. Photosensitization has been reported to occur. Coal tar should not be used on cats, because of frequent irritant or allergic reactions. Camphor is a rubefacient that has been used in some topical preparations and has some mild analgesic activity. It is of limited use in the treatment of mild pruritus. Similarly, menthol stimulates sensory nerve endings, inducing a feeling of coolness, induces mild analgesia, and is also a mild antipruritic (Harvey, 1985).

Caustics and Escharotics

Caustics (also known as *corrosives*) are agents that will destroy tissue after one or more applications. Escharotics are corrosive and will also precipitate proteins, leading to the formation of a scab and eventually a permanent scar. As with the rubefacient, irritant, and vesicant group, many of the caustics and escharotics have few uses in veterinary dermatology today. Historically, caustics have been used to induce desquamation of the stratum corneum (keratolytic) and to treat warts, keratoses, and other hyperplastic skin diseases. Escharotics have also been used to seal cutaneous ulcers and wounds. Examples of this group include glacial acetic acid, alum, aluminum chloride, gentian violet, phenol, potassium hydroxide, salicylic acid, and silver nitrate.

Keratolytics, Keratoplastics, and Antiseborrheics

Keratolytics function by loosening keratin, which facilitates the desquamation of the stratum corneum, whereas keratoplastics attempt to "normalize" keratinization by slowing basal cell proliferation through inhibition of DNA synthesis. Other mechanisms may also contribute to this effect. Antiseborrheics attempt to modulate sebum production in the skin. Many of the keratolytics available today are also keratoplastic and/or antiseborrheic; therefore, these functions are discussed together. Most keratolytics and antiseborrheics are also cutaneous irritants, which may, in some cases, preclude their use on diseased skin in some animals (Shanley, 1990). Several keratolytics and antiseborrheics used in veterinary dermatology are discussed here.

Salicylic acid (2-hydroxybenzoic acid) is used topically as a keratolytic, keratoplastic, and antiseborrheic agent and has some mild antibacterial and antifungal actions. Salicylic acid (2–10%) causes the dead or dying cells of the stratum corneum to hydrate, swell, and soften, thereby hastening their desquamation, and solubilizes the intercellular lipid layer, releasing the cells of the stratum corneum from each other. Salicylic acid is used extensively in veterinary dermatology to treat many keratoproliferative diseases. Topical use of salicylic acid may cause an irritant dermatitis in animals and has been studied extensively in both humans and many animal models (Weirich, 1975; Nook, 1987; de Mare et al., 1988; Sloan et al., 1986; Roberts and Horlock, 1978).

Benzoyl peroxide is a keratolytic and antiseborrheic agent that is also a strong oxidizer, free-radical generator, and antimicrobial and has been used in veterinary and human dermatology for many years. It important to note that products for people contain higher concentrations of benzoyl peroxide (5–10%) than the veterinary products (2.5–3%). Thus human products should *not be used* on animals due to the increased sensitivity of animals to the irritant properties of this ingredient. The majority of topically applied benzoyl peroxide is metabolized to benzoic acid by the viable epidermal cells during penetration through the skin (Holzmann et al., 1979; Nacht et al., 1981). Benzoyl peroxide in high concentrations can cause skin irritation and was identified as being a skin tumor promoter in SENCAR mice if used in tandem with 7,12-dimethylbenz(a)-anthracene (Slaga et al., 1981; Epstein, 1988; Schweizer et al., 1987). The bactericidal activity associated with benzoyl peroxide comes from its ability to generate free radicals, which disrupt bacterial cell membranes. Due to its bactericidal activities, benzoyl peroxide is indicated in the treatment of pyodermas (Ihrke, 1980a, 1980b) as well as in diseases that cause keratosis. Benzoyl peroxide is believed to have follicular flushing properties and it is useful in diseases with comedone formation such as demodicosis and actinic dermatoses. Transient stinging or burning sensations after application to the affected site have been reported in humans.

Resorcinol (*m*-dihydroxybenzene) is a keratolytic agent that also has bactericidal and fungicidal properties. Like urea (discussed below in this section), it acts as a protein precipitant and promotes hydration of the keratin, resulting in its keratolytic function. Resorcinol may be used alone or compounded with other mild keratolytic agents, such as sulfur or salicylic acid.

Sulfur is a keratolytic, keratoplastic, and antiseborrheic agent used in a variety of topical agents. Sulfur is also antibacterial and antipruritic and has a mild follicular flushing action. The keratolytic activity of elemental sulfur is thought to be related to an inflammatory process that ultimately causes a sloughing of the stratum corneum. The formation of hydrogen sulfide and pentathionic acid is responsible for some of its keratolytic and antibacterial properties. The keratoplastic effect is most likely similar to that of the coal tars, being cytostatic (Miller, 1986). Retinoids are a class of naturally occurring or synthetically manufactured compounds that have vitamin A-like (retinoic acid) activity. Retinol (vitamin A alcohol) is the most potent analog and is metabolized to two other retinols, retinal and retinoic acid. In the early 20th century, researchers documented the importance of vitamin A in reproduction, vision, and epidermal cell growth promotion, along with its functions in differentiation and maintenance of epithelial cell surface structure, including that of the skin (Kwochka, 1989). It was also found that *some* dyskeratotic skin diseases could be correlated to low levels of vitamin A, which eventually led to the therapeutic use of vitamin A to treat these skin diseases. The use of vitamin A was limited, however, as the levels needed to induce a clinical improvement of the lesions often induced signs of hypervitaminosis A. This side-effect dilemma prompted research into vitamin A substitutes, which led to the discovery and testing of over 1,500 retinoids. Three retinoids – tretinoin, isotretinoin, and etretinate – are available for clinical use today.

The retinoids, like vitamin A, act as growth and differentiation regulators in the skin when administered orally or topically. Although the exact mechanism by which the retinoids exert these effects is not completely understood, it is theorized that retinoids alter RNA synthesis within the cell, in turn altering protein synthesis and prostaglandin production, and also affecting some enzymes, such as ornithine decarboxylase and collagenase (Power and Ihrke, 1990). The overall effect of the retinoids is to “normalize” the epithelium in those diseases responsive to these drugs.

In humans, the retinoids are used to treat severe recalcitrant cystic acne, psoriasis, Darier’s disease, pityriasis rubra pilaris, and various other disorders of keratinization. Retinoids also have an ability to control malignant transformations in some tissues that are caused by chemical carcinogens, ionizing radiation, growth factors, and viruses. Naturally occurring retinoids have been shown to protect animals against skin papillomas and carcinomas of the skin and other organs (Griffiths and Vorhees, 1994; Kwochka, 1989). Numerous side effects have been associated with retinoid use in humans, including cheilitis, xerosis of the skin, pruritus, dryness of mucous membranes, epistaxis, thinning of the hair, palmoplantar desquamation, conjunctivitis, headache, ataxia, fatigue, psychological changes, and visual disturbances. Tetragenicity is a serious problem in women who take isotretinoin during pregnancy. Symptoms of hypervitaminosis A may also occur, which is characterized by demineralization and thinning of the long bones, cortical hyperostosis, periostitis, and premature closure of the epiphyses (Kwochka, 1989).

Retinoids are not used to a great extent in veterinary medicine (Werner and Power, 1994). Reported uses of any of the retinoids in dogs and cats are few, and the recommendations for use and possible toxicities and side effects are based on a very small number of animals. Indications for veterinary use remain rather vague, in part because the skin diseases that retinoids may be efficacious in treating in humans do not have exact analogs in domestic animals. There is also a lack of formal studies conducted on large populations of dogs or cats. Reported uses for the retinoids in domestic animals are in disorders of keratinization, which may include primary idiopathic seborrhea in Cocker Spaniels, sebaceous adenitis, canine lamellar ichthyosis, Schnauzer comedo syndrome, and epidermal inclusion cysts, among others (Power and Ihrke, 1990; Kwochka, 1989). The use of retinoids in cats with neoplastic disorders, specifically squamous cell carcinoma and epidermal dysplasia, has been investigated and found to be of limited value (Evans et al., 1985). Toxicities to the retinoids in animals seem to be few, but it should be made clear that the reported side effects and toxicities are based on a small population of clinically ill animals treated for short periods of time with these compounds and these observations may prove to be inaccurate if the use of these compounds increases. Out of 29 dogs treated with isotretinoin in one study (Kwochka, 1989), four dogs developed conjunctivitis that was observed to be reversible after treatments ended. There is no formal information available as to the existence of skeletal anomalies in dogs given retinoids for long periods of time (Power and Ihrke, 1990). Birth defects involving the central nervous system, skeleton, thymus, and heart do occur, as seen with high doses of vitamin A during pregnancy. Cats appear to have a higher incidence of side effects associated with retinoid treatment. Cats treated with isotretinoin were observed to develop periocular erythema, periocular crusting, epiphora, and blepharospasm (Kwochka, 1989).

Isotretinoin (Accutane, Roche; 13-*cis*-retinoic acid) and etretinate (Tegison, Roche) are two systemically used retinoids that also have potential veterinary applications. Power and Ihrke (1990) describe several cases where these two retinoids have been used to treat several skin diseases in dogs, with variable success. Isotretinoin is the most effective inhibitor of sebum production known (Kwochka, 1989), making it potentially useful in treating primary idiopathic seborrhea and comedo syndromes. Although retinoids are associated with less toxicity than vitamin A, toxicities can occur. Etretinate may be associated with fewer toxic side effects than isotretinoin. Insufficient data are available for dogs or cats to determine its efficacy or toxicity.

Coal tar is another pharmaceutical that has keratolytic as well as keratoplastic and antiseborrheic activity. Its mechanism of action and general uses have been discussed previously. Coal tar products should not be used in the feline due to frequent irritant reactions and increased risk of toxicity.

Urea is a product of protein metabolism that, when used topically, acts as a protein denaturant, promoting the hydration of keratin. Once the treated areas of keratin swell, mild keratolysis ensues. The use of urea alone as a keratolytic agent is not common in veterinary dermatology today.

Selenium sulfide is an externally applied antiseborrheic, keratolytic, and keratoplastic compound that also has some antidandruff activities. Selenium sulfide exerts these actions by its antimitotic activity, slowing cell proliferation and sebum production, and tends to be irritating (especially if used in long-term treatment protocols) and also stains hair. It also causes irritation of the mucous membranes, so care should be taken to avoid contact with these tissues. Percutaneous absorption is minimal if applied to intact skin. Selenium disulfide is very useful in treating oily seborrheic disease caused by Malassezia. This ingredient is well tolerated by dogs but should not be used on cats.

Classes of Medicated Applications

Pharmaceuticals can also be classified by the type of base in which they are formulated. There are eight classes of medicated applications (Harvey, 1985; Block, 1985; Rippie, 1985; Swinyard, 1985; Swinyard and Lowenthal, 1985; Nairn, 1985).

Ointments

Ointments are semisolid preparations that usually (but not always) contain drugs used to treat dermatological diseases. There are five classes of ointments commonly used in veterinary medicine.

Hydrocarbon Bases

These emollient ointment bases usually are composed of vegetable oils and animal fats. Common members of this subset include spermaceti, cetyl esters wax ("synthetic spermaceti"), oleic acid, olive oil, paraffin, petrolatum, white petrolatum, white wax, and yellow wax. Hydrocarbon base ointments are emollient and generally hydrophobic and occlusive, causing an increase in the hydration of the stratum corneum and underlying epidermal cell structure by decreasing transepidermal water loss, making them useful in rehydrating or softening the skin. Disadvantages include greasiness and their ability to stain clothing; also, they cannot be washed off in water, making them difficult to completely remove from the skin.

Anhydrous Absorption Bases

This type of ointment base contains very little (if any) water after preparation but differs from the hydrocarbon bases in that it will readily accept any water molecules it comes in contact with. Absorbent ointment bases can absorb large quantities of water and still keep their thick consistency. Examples of this subgroup include hydrophilic petrolatum and anhydrous lanolin, both of which are emollient, occlusive, and greasy.

Water–Oil Emulsion Bases

Emulsions, by definition, are oil and water combinations. Water-in-oil emulsion bases ("creams") are water-washable bases that are easily removed from the skin surface and contain more oil than water on a percentage basis. The oil phase usually consists of petrolatum or liquid petrolatum and perhaps an alcohol (cetyl or stearyl alcohol). The aqueous phase may consist of water; however, other aqueous vehicles may be used, such as propylene glycol, polyethylene glycol, or glycerin, to which various preservatives (such as paraben derivatives) are usually added. Water-in-oil bases are emollient (due to the higher percentage of oil than aqueous phase), occlusive, greasy, and may absorb some water, but not to the same degree as the anhydrous absorption bases. Other common components of water-in-oil emulsion bases include glyceryl monosterate and stearic acid.

Oil–Water Emulsion Bases

Oil-in-water emulsions are manufactured in the same manner as the water-in-oil bases, with the exception that the aqueous phase is in a higher percentage than the oil component. The same ingredients are also used to make the oil-in-water bases. Because of the higher water (or other aqueous phase) content, oil-in-water bases are water washable, nongreasy, and nonocclusive.

Water-Soluble Bases

As the name implies, these bases have lost their hydrophobic lipid base components. These demulcent bases are primarily composed of polymers that are completely water soluble and usually anhydrous, do not easily hydrolyze, do not support mold growth, and are nongreasy, nonocclusive, and nonvolatile. If the components of a preparation contain water-soluble bases in a gelled medium, they are referred to as *gels*. Gels are a combination of propylene glycol, propylene gallate, disodium EDTA, and carboxypolymethylene that results in a clear, water-miscible, and relatively greaseless formulation. A commonly used drug in a gel formulation is DMSO (Domoso, Diamond), discussed in Section Penetration Enhancers. Among other drugs, glucocorticosteroids may also be formulated in this way.

Poultices

A poultice (or cataplasm) is a soft moist mass of materials applied locally to an affected area and was historically composed of roots, herbs, seeds, and even mud in a gruel-like base. The poultice was intended to be a topical wound treatment serving as a counterirritant and absorptive/adsorptive sink. Poultices are rarely used in veterinary medicine today.

Pastes

Pastes are absorptive powders placed in a gelatinous base, usually petrolatum or hydrophilic petrolatum. Pastes have been used to adhere to the skin and thereby act as a “sponge” to absorb exudates and moisture and also as a physical barrier to protect the skin from the external environment. Pastes are easily removed from the skin and can be used on moist lesions of the skin.

Powders

Powders have been discussed in Section Adsorbents and Protectives as a class of vehicle for the delivery of topical drugs to the skin. Powders are commonly used in veterinary medicine to deliver pesticides (carbaryl, permethrins, etc.) for the control of external parasites (mainly fleas) and in large animal veterinary dermatology to deliver antibiotics, such as nitrofurazone, to wounds.

Dressings

Dressings are external applications of some previously discussed compounds (petrolatum, ointments) on an application device such as plastic wrap or sterile gauze and are placed over wound sites to protect the skin lesion from external environmental trauma. Dressings may also contain antimicrobial agents, such as nitrofurazone.

Plasters

Plasters are similar to dressings; however, they are attached to the skin via some adhesive material. They protect skin lesions from the external environment and provide an occlusive environment. Plasters have limited use in veterinary medicine today.

Suspensions

A suspension is a two-phase system composed of a finely divided solid that is dispersed in a liquid, usually water. Suspensions are not utilized to any great degree in veterinary dermatology today. They are more commonly used in oral drug preparation schemes. The most common type of suspension currently used topically is captan (Orthocide, Chevron Chemical), which is used to treat some types of superficial fungal infections and which also has some limited bacteriostatic properties.

Lotions

Lotions are powders dissolved in a liquid, usually water or an alcohol. Lotions, like powders, tend to be cooling, drying, and somewhat mildly antipruritic. Lotions have limited applications in veterinary medicine but are used extensively in human over-the-counter skin-care products.

Dermatotherapy: Atopic Dermatitis

One dermatological disease – atopic dermatitis – deserves specific mention because it is a common clinical syndrome with various stages of presentation and potential initiating etiologies. A systematic review of randomized controlled trials (RCTs) for canine atopic dermatitis reviewed a total of 49 RCTs, which had enrolled a total of 2126 dogs (Olivry et al., 2010). This review found some evidence of efficacy for topical tacrolimus (three RCTs), topical triamcinolone (one), oral glucocorticoids (five), oral cyclosporine (six), subcutaneous recombinant gamma-interferon (one), and subcutaneous allergen-specific immunotherapy (three) to decrease pruritus and/or skin lesions of atopic dermatitis in dogs as monotherapy. One high-quality RCT showed that an oral essential fatty acid supplement has a significant steroid-sparing effect, so although essential fatty acids may not be sufficiently strong to be used as monotherapy, they have a positive effect in decreasing the prednisolone consumption by approximately half. Chapter 29 should be consulted for a complete introduction to glucocorticoids.

When interpreting the results of reviews aimed to make recommendations based on the level of evidence for efficacy of a treatment, it is important to note the difference between reporting evidence of efficacy on a review and the clinical usefulness of such treatment. For example, although evidence of efficacy has been found for interferon, this is not a treatment used in the clinics. Similarly, although evidence was not found for drugs such as antihistamines (a class of drugs fully discussed in Chapter 19), these are still commonly used in the clinics (Zur, 2002) and often with good client satisfaction (Dell, 2012). Antihistamines are best used for their steroid-sparing effects rather than as monotherapy. The lack of reported evidence is frequently due to the lack of large controlled clinical trials and the unrealistic expectation of using antihistamines as monotherapy. Thus the lack of evidence of efficacy reported in the metaanalysis should not be equated with a lack of clinical benefit. It is still recommended to try different antihistamines to find the most helpful in individual cases and to use them in conjunction with other therapies (DeBoer, 2001).

A small more recent trial reported on the beneficial effect of various antihistamines (Eichenseer et al., 2013). In published treatment guidelines for canine atopic dermatitis (Olivry et al., 2015), the importance of controlling both the acute flare ups and prevent more flare ups in the long term is highlighted. The best control of symptoms is typically achieved with a *multimodal approach,* which involves topical therapy (with the intent to both remove the allergen from the coat, decrease inflammation and pruritus with topical glucocorticoids, and improve skin barrier function with moisturizers and topical ceramides) and systemic therapy. With this approach the clinician aims to decrease the level of pruritus below the threshold of clinical signs. Using a multimodal approach, it is common to use lower doses of medications than would be needed to control signs if they were used alone. Additionally, it is important to remember that in many patients environmental allergens absorbed epicutaneously function as important triggers. Thus the removal of those allergens on a routine basis in conjunction with mild hypoallergenic products that improve, or minimally do not worsen, the skin barrier is of great help in many patients. Drugs used for the acute flare ups include topical and oral glucocorticoids and oral oclacitinib (Olivry et al., 2015). Within the topical options, oatmeal and topical anesthetic like pramoxine are frequently used both as shampoos and as leave-on conditioners. In cases of more severe pruritus, topical triamcinolone (triamcinolone 0.015%, Genesis®, Virbac) has been used with good clinical response and minimal adverse effects with prolonged use (DeBoer, 2002). This product is currently not available on the market. Another topical glucocorticoid (1% hydrocortisone, Resicort®, Virbac,) has been used frequently in clinical practice. This product also is currently not available on the market. In Europe, the efficacy of a 0.0584% hydrocortisone aceponate spray (Cortavance(®); Virbac) and cyclosporine (Atopica(®); Novartis Animal Health) in canine atopic dermatitis was found to be comparable in a single-blind randomized controlled trial (Nuttall et al., 2012). Similar proportions of dogs treated with hydrocortisone aceponate spray or cyclosporine achieved ≥50% reductions in CADESI-03 and pruritus scores at 28 days, providing a topical option for affected dogs. This product is not available at this time in the USA.

The long-term effect of topical glucocorticoids is cutaneous atrophy; thus the short-term benefit of controlling pruritus and inflammation is exchanged with the potential for cutaneous atropy if the product is used too often. An alternative option to topical glucocorticoids is the use of topical tacrolimus, discussed in Chapter 45. This approach was developed in human medicine to address the issue of cutaneous atrophy seen with the steroids. Tacrolimus is a calcineurin inhibitor that does not induce cutaneous atrophy and actually improves skin barrier function (Chittock et al., 2015; Dähnhardt-Pfeiffer et al., 2013). One of the undesirable adverse effects of tacrolimus is the stinging and burning sensation that is frequently observed at the beginning of treatment. While in most cases this is a transient adverse effect, many patients elect to discontinue therapy. Another undesirable characteristic of topical tacrolimus is the fact that it comes formulated as a thick ointment that it is messy and greasy on application. The efficacy of tacrolimus for canine atopic dermatitis has been evaluated. A significant reduction in lesional scores has been reported in dogs with localized disease (Bensignor and Olivry, 2005) after 6 weeks of therapy using the 0.1% formulation. Dogs with localized disease respond better than dogs with generalized disease (Marsella et al., 2004a). While the efficacy of tacrolimus was found to be good, the fact that in many dogs the disease was localized to the feet and that this treatment would trap dirt on the hair, the compliance and satisfaction of owners was diminished by the logistics and cosmetics of the treatment. Although some absorption occurs after topical administration, levels were well below toxicity thresholds and this formulation was well tolerated in dogs (Marsella et al., 2004a). In contrast to glucocorticoids, which suppress intradermal skin test reactivity, tacrolimus has no significant effect on immediate reactions after intradermal injection of allergens; thus no withdrawal is necessary prior to testing in patients receiving topical tacrolimus (Marsella et al., 2004b).

Several studies have been conducted on the efficacy of sphingolipid emulsions containing a mixture of ceramides and fatty acids. These products have been shown to improve skin barrier of atopic dogs both ultrastructurally, as shown on electron microscopy, and functionally, as measured by transepidermal water loss (Jung et al., 2013). The improvement of skin barrier corresponds to an improvement of clinical signs (Jung et al., 2013). Normalization of the ultrastructure of the epidermis after this form of treatment occurs parallel to normalization of epidermal lipids (Popa et al., 2012). It is important to note that this type of therapy is most successful when considered as adjunctive therapy rather than as sole therapy and when used for at least a month (Fujimura et al., 2011).

As stated in the published guidelines on the treatment of canine atopic dermatitis (Olivry et al., 2015), it is important to both control acute flare up and have a long-term approach to minimize the occurrence of flare up. For the long-term approach, the most effective therapy still remains allergen-specific immunotherapy. This approach has been shown in human medicine to alter the course of the disease and minimize development of new allergies.

Oral glucocorticoids have been traditionally used to control signs of atopic dermatitis. The most commonly used are prednisone and prednisolone, either alone or in combination with trimeprazine (Paradis et al., 1991). A synergistic effect of prednisolone and trimeprazine has been postulated since a decreased dose of prednisolone is sufficient to control signs when used in combination. With long-term use of glucocorticoids, decreased efficacy is common, necessitating a change to a different form of therapy.

A new and very effective drug for the treatment of canine atopic dermatitis is oclacitinib, a JAK1 inhibitor. Janus kinases (JAK) are tyrosine kinases responsible for modulating cytokine production in some cells. Oclacitinib was shown to be very selective for JAK1 and some effect on JAK3 but no effect on JAK2. Thus the effect is targeted on the suppression of cytokines involved in inflammation and allergy (IL-6, IL-2, IL-4, IL-13) but no effect on cytokines involved in hematopoiesis (Gonzales et al., 2014). Oclacitinib does not have any of the adverse effects reported for JAK inhibitors used in human medicine. Oclacitinib is rapidly and well absorbed after oral administration with a peak concentration within the first hour and a bioavailability of 89% (Collard et al., 2014). Food does not interfere with its absorption and no drug interactions have been reported at this time.

In a clinical trial using privately owned dogs diagnosed with allergic dermatitis, oclacitinib had rapid onset of efficacy, being more effective than placebo starting after the first 24 hours of administration based on pruritus evaluation done by owners (Cosgrove et al., 2013b). By the end of the first week (when dogs were rechecked and evaluated by the veterinarian), significant differences were recorded for both pruritus and skin lesions. The same excellent response was confirmed when oclacitinib was administered to dogs specifically diagnosed with atopic dermatitis and evaluated by dermatologists (Cosgrove et al., 2013a). Dogs were randomized to receive either oclacitinib (0.4–0.6 mg/kg twice daily for 14 days and then once daily for up to 112 days) or an excipient-matched placebo. On days 14 and 28, dermatologists recorded a 48.4% reduction in CADESI-02 scores in oclacitinib-treated dogs compared with a 1.7% reduction and a 3.6% increase in placebo-treated dogs. After day 28, >86% of all placebo-treated dogs had moved to an open-label study.

When the efficacy of oclacitinib was compared to existing therapies such as oral prednisolone (0.5–1.0 mg/kg once daily for 6 days, then every other day) it was found that both treatments produced a rapid onset of efficacy within 4 hours. The mean reductions in pruritus and dermatitis scores were not significantly different between the treatments except on day 14, when reductions were more pronounced for oclacitinib than prednisolone, based both on owner pruritus and veterinarian dermatitis scores (Gadeyne et al., 2014). Adverse events were reported with similar frequency in both groups. When oclacitinib was compared to oral cyclosporine, it was found that oclacitinib had a faster onset of action and a lower frequency of gastrointestinal side effects compared with cyclosporine (Little et al., 2015).

Oclacitinib is labeled for use in dogs older than 12 months due to reports of demodicosis when administered to younger dogs. According to the label, this drug is recommended at a dose of 0.4–0.6 mg/kg twice daily for the first 2 weeks, followed by once daily for long-term treatment. A decrease in control of symptoms is very common when switching from the twice to the once-daily administration. In an uncontrolled study on compassionate use of oclacitnib for long-term management of atopic dermatitis (Cosgrove et al., 2015), an improvement in quality of life was reported by owners in over 90% of cases. An increased risk for development of infections is reported for oclacitinib, as it is also seen for long-term use of glucocorticoids and cyclosporine. It is currently not known if oclacitinib increases risk of developing cancer, as the study on long-term use (up to 630 days) was not controlled. With a lack of polyuria, polydipsia is considered an improvement when compared with glucocorticoids, as is the rapid onset of effect and lack of potential for drug interactions relevant with cyclosporine (Gray et al., 2013), and minimal GI adverse effects, which are also an improvement compared to cyclosporine.

Due to issues with availability of oclacitinib, many patients not able to tolerate glucocorticoids are still maintained with oral cyclosporine. This therapy has been available for over a decade (Nuttall et al., 2014; Archer et al., 2014), and demonstrates an overall good profile of efficacy and owner satisfaction (DeBoer, 2014). Chronic cyclosporine administration is generally safe, with vomiting and diarrhea being the most common adverse effects which can be a limiting factor for many patients. In some cases, freezing the capsules may help to decrease vomiting. Administration of metoclopramide may also decrease emesis. Adverse effects in 55% of dogs have been reported in clinical trials. Besides the gastrointestinal problems (seen in 25% of dogs in the first month of therapy), the most common reported side effects are gingival hyperplasia, and papillomatous and psoriasiform dermatitis, which tend to respond to a decrease in cyclosporine dose. Hirsutism can be seen rarely (less than 1 % of reported cases). Monitoring of blood concentrations is not justified since specific blood concentrations are not linked to clinical efficacy. The clinical relevance of the reported effect of cyclosporine on glucose metabolism (Kovalik et al., 2011) is minimal, as is its effect on calcium metabolism (Kovalik et al., 2012). A topical formulation of cyclosporine has been tested with good success and may provide an alternative for dogs that cannot tolerate oral administration (Puigdemont et al., 2013). This was made possible by developing nano-size formulation, which allows for the penetration of cyclosporine in the skin. However, this is not commercially available for prescription in clinical cases.

An antibody against IL-31 has received conditional approval by USDA for the treatment of canine atopic dermatitis as a subcutaneous injection, once a month. Data on its efficacy and safety in dogs has not been published yet, but this treatment modality has great potential since IL-31 is an important mediator of pruritus in dogs (Gonzales et al., 2013).

In summary, the treatment of canine atopic dermatitis requires a multimodal approach tailored to the specific needs of the patient that utilizes both topical and systemic options and relies on the identification and correction of all trigger factors.

Drugs that Affect the Respiratory System

Mark G. Papich

Antitussive Drugs

Cough Reflex

The afferent arc of the cough reflex receives input from sensory nerves in the bronchial and tracheal airways. Airway irritation and inflammation stimulate the afferent nerves, which in turn activate the cough center located in the medulla oblongata.

Mechanism of Action of Antitussive Drugs

The antitussive drugs directly depress the cough center in the medulla. The site of action may be either μ- or κ-opiate receptors (discussed in Chapter 13). Opiate drugs that act on these receptors are effective, but it is not simply because they produce sedation (Morjaria et al., 2012). Either of the opiate receptors may be responsible for the action because both butorphanol (κ-receptor agonist) and codeine or morphine (μ-receptor agonists) can suppress cough (Takahama and Shirasaki, 2007; Gingerich et al., 1983; Christie et al., 1980; Morjaria et al., 2012), but naloxone is capable of antagonizing this effect.

There may be a nonopiate mechanism for some antitussives as well (Morjaria et al., 2012). For example, dextromethorphan is an opiate derivative, but does not have activity at opiate receptors and may bind to sites in the brain that are distinct from opiate receptors. It is continues to be marketed as an over-the-counter (OTC) antitussive for people – apparently based on early clinical trials. Its mechanism is unknown. The neurokinin receptor (NK) may play a role in antitussive activity of such nonopiates. This mechanism has not been well characterized (Takahama and Shirasaki, 2007), but is discussed further with the NK-1 receptor antagonist drugs below. Beta-2 receptor agonists (β_2) will suppress cough in some animals. The effect of these drugs is mediated via bronchodilation. These drugs will be discussed in Section Bronchodilator Drugs (β-Adrenergic Receptor Agonists).

Use as preanesthetics: Opioids are administered as premedications prior to surgery. This provides a sedative effect, analgesia, and also may facilitate intubation. Inhibition of the cough reflex may decrease laryngeal spasms and coughing associated with intubation during anesthesia induction.

Morphine

Morphine and derivatives have opiate-receptor–mediated effects, but also are effective as antitussives. Morphine is a natural derivative of one of the alkaloids of opium (Chapter 13). Morphine is the prototype of an opiate (narcotic) analgesic with good binding affinity for the μ- and κ-opiate receptors. Morphine can be administered at low doses that produce antitussive effects without causing analgesia and sedation. The antitussive dose has been reported to be approximately 0.1 mg/kg, q 6–8 h. Morphine is not regularly used as an antitussive because of the side effects and potential for abuse and addiction in humans. Oral formulations of morphine do not have good systemic absorption in dogs (see Chapter 13).

Codeine (Methylmorphine)

Codeine phosphate and codeine sulfate are found in many preparations including tablets, liquids, and syrups. There are over 50 different combinations and preparations of codeine. However, codeine oral absorption in dogs is low and inconsistent.

Codeine has analgesic effects that are approximately 1/10 that of morphine. Studies in people have shown little benefit from codeine for cough suppression, but the small amount of codeine metabolized to morphine may produce an antitussive effect. In dogs codeine administered orally attains systemic levels of only 4% (KuKanich, 2010), but it is possible that other metabolites may be responsible for the antitussive effect. Despite the occasional use in dogs, the efficacy for treating cough has not been studied. It is available as

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

15, 30, and 60-mg tablets and oral syrups (2 mg/ml). In some states (regulated by local regulations), and some countries, codeine in antitussive formulations may be obtained without prescription.

In people, the side effects of codeine at antitussive doses are significantly less than those experienced with morphine. The potential for addiction and abuse is considerably lower. Important side effects include sedation and constipation.

Hydrocodone

Hydrocodone is similar to codeine in mechanism of action, but it is more potent. Hydrocodone is combined with an anticholinergic drug (homatropine) in the preparation Hycodan®, which has been prescribed often for small animals. Pharmacokinetic studies have shown that is absorbed orally in dogs but there is conflicting evidence in dogs on the metabolism to hydromorphone (Benitez et al., 2015). It is possible that the antitussive effect is produced by a different metabolite. Nevertheless, some veterinarians consider it their first drug of choice for symptomatic treatment of cough in dogs. The anticholinergic component (homatropine) is added to discourage abuse rather than for a respiratory indication. Oral doses administered to dogs are approximately 0.22–0.25 mg/kg, q 6–8 h (approximately 1 tablet per 20 kg).

Available Products

Hydodan® is a combination product with hydrocodone bitartrate formulated as 5 mg of hydrocodone + 1.5 mg homatropine. In some countries it is available without an anticholinergic (5 mg). Hydrocodone (5 mg) + acetaminophen (500 mg) is combined in a tablet and used for analgesia (Vicodin). Because of the acetaminophen in these products, they should never be used in cats. In dogs, high acetaminophen exposure may result from the high doses necessary. In the United States recently, hydromorphone was rescheduled by the DEA from Schedule III, to Schedule II, which makes prescribing more restrictive.

Dextromethorphan

Dextromethorphan is not a true opiate because it does not bind μ- or κ-opiate receptors, but studies in people have supported its antitussive effects. More recent investigations have questioned the antitussive properties of OTC formulations.

Dextromethorphan is the ᴅ-isomer of levorphan (the ʟ-isomer, levorphan is an opiate with addictive properties, but the ᴅ-isomer is not). Dextromethorphan produces mild analgesia and modulates pain via its ability to act as an NMDA (*N*-methyl ᴅ-aspartate) antagonist, but this is unrelated to the antitussive action (Pozzi et al., 2006).

Clinical Use

Dextromethorphan has been administered to dogs and cats, but pharmacokinetic studies in dogs indicated that dextromethorphan does not attain effective concentrations after oral administration (KuKanich and Papich, 2004a). After IV injection it produced adverse effects in dogs (vomiting after oral doses, and central nervous system reactions after IV administration). Even after IV administration, concentrations of the parent drug and active metabolite persisted for only a short time after dosing. Therefore, routine use in dogs is not recommended until more data are available to establish safe and effective doses.

Formulations

There are many preparations available without a prescription (OTC) in liquid and tablet form. For example, Vicks Formula 44® and Robitussin® contain dextromethorphan as their active antitussive ingredient. OTC formulations may vary in concentration, but most contain 2 mg/ml, or 15 or 20 mg per tablet. Pet owners should be cautioned that many OTC preparations contain other drugs that may produce significant side effects. For example, some combinations also contain acetaminophen, which can be toxic to cats. Some preparations also contain a decongestant, such as pseudoephedrine, which can cause excitement and other side effects.

Butorphanol (Torbutrol®, Torbugesic®)

Butorphanol is an opioid agonist–antagonist that has been used both as an analgesic and antitussive. It has been a potent antitussive with clinical studies that support its use in dogs (Gingerich et al., 1983; Christie et al., 1980). High doses may induce side effects such as sedation.

Butorphanol is poorly bioavailable because of oral first-pass metabolism. Therefore, in dogs the oral dose is higher (0.55 to 1.1 mg/kg) than the IV or SC dose (0.05 to 0.1 mg/kg). It is administered as frequently as needed to control cough – usually every 6 to 12 hours. In clinical studies the peak effect was rapid after the injectable formulation. After oral administration, the maximum effects were observed for 4 hours but persisted for up to 10 hours in dogs (Gingerich et al., 1983). By contrast, codeine’s effect in dogs is much shorter. It is available as 1, 5, and 10-mg tablets and an injectable solution.

Tramadol (Ultram and Generic)

Tramadol is an inexpensive oral drug used for analgesia. It possesses opiate, serotonin, and α_2 activity. (The pharmacology of tramadol is discussed in more detail in Chapter 13). The active metabolite has opiate activity and is believed to be responsible for most of the analgesia. This drug also has antitussive properties and appears to be well tolerated in dogs, and it is not a controlled substance. However, efficacy for treating cough in dogs has not been evaluated. The recommended oral dose is 5 mg/kg, every 6 hours, but this has not been tested for antitussive efficacy (KuKanich and Papich, 2004b).

Bronchodilator Drugs (β-Adrenergic Receptor Agonists)

The β-adrenergic receptor agonists have a beneficial effect in the treatment of some airway diseases. They are used commonly in people for the treatment of asthma. In animals, they are used for airway disease, allergic bronchitis, and similar diseases such as feline "asthma," recurrent airway obstruction (RAO) ("*heaves*"), and inflammatory airway disease (IAD) in horses. The autonomic properties are discussed in more detail in Chapter 7 of this textbook, and the application to respiratory diseases will be included here.

Mechanism of Action

Bronchial smooth muscle is innervated by β_2-adrenergic receptors. Stimulation of β_2 receptors leads to increased activity of the enzyme adenylate cyclase, increased intracellular cyclic adenosine monophosphate (cyclic-AMP), and relaxation of bronchial smooth muscle (see Chapter 7).

Stabilize Mast Cells

Stimulation of β-receptor activity on mast cells decreases release of inflammatory mediators. The β receptor on mast cells produces a stabilizing effect (inhibition of mediator release) (Chong et al., 2002). There is little effect on other inflammatory cells. Therefore, when airway inflammation is mediated by neutrophils and/or eosinophils, this property of the β agonists may be less important. Cytological examination of fluid from a tracheal wash or bronchoalveolar lavage may help in making this distinction.

Increased Mucociliary Clearance

There is some evidence that β-adrenergic receptor agonists increase mucociliary clearance in the respiratory tract. The clinical significance of this effect has not been established (Norton et al., 2013).

Clinical Use

The β agonists discussed below should be used for short-term relief of bronchospasm. They should be avoided for long-term use as repeated administration may diminish the response because of a change in receptors after prolonged exposure. The receptor changes during chronic administration are a result of down-regulation and desensitization. Concurrent use of corticosteroids may attenuate the desensitization. For management of airway diseases, other drugs (e.g., corticosteroids) can be used for long-term maintenance, and β agonists used short term during acute exacerbations of bronchoconstriction.

Short-Acting Nonspecific Bronchodilators

Epinephrine (Adrenaline)

Epinephrine stimulates α- and β-adrenergic receptors (Table 48.1). It produces pronounced vasopressive and cardiac effects. Epinephrine is considered the drug of choice for the emergency treatment of life-threatening bronchoconstriction, such as during an anaphylactic reaction. The nonspecific stimulation of other receptors and its short duration make it unsuitable for long-term use. The dose used in animals is 10 μg/kg IM or IV administered as a one-time treatment, or repeated in 15 minutes. Formulations are available in either 1 : 10,000 concentration (0.01%, 0.1 mg/ml) or 1 : 1,000 concentration (0.1%, 1 mg/ml). Duration of action is short (less than 1 hour). Norepinephrine (Levarterenol) has similar β_1 effects as epinephrine but fewer α_1 and β_2 effects, and therefore is not suitable for respiratory therapy.

Table 48.1 Relative effects of catecholamines and adrenergic agonists on adrenergic receptors

Drug	α_1	β_1	β_2	DA
Norepinephrine (noradrenaline)	+++	1	0	0
Epinephrine (adrenaline)	+++	+++	++	0
Ephedrine	+++	+++	+++	0
Dopamine (Intropin®)	+++	+++	+	++++
Dobutamine (Dobutrex®)	+	+++	+	0
Isoproterenol (Isuprel®)	0	+++	++++	0
Isoetharine (Bronkosol®)	0	+	+++	0
Metaproterenol (Alupent®)	0	+	++	0
Terbutaline (Bricanyl®)	0	+	+++	0
Albuterol, Salbutamol (Ventolin®)	0	+	+++	0
Clenbuterol (Ventipulmin®)	0	+	+++	0

DA, dopamine.

Isoproterenol (Isuprel)

Isoproterenol is a potent β receptor agonist. It is selective for β receptors with little α-receptor–mediated effects, but the cardiac (β_1) effects make it unsuitable for long-term use. It has been administered by inhalation or injection. It has a short duration of action (less than 1 hour).

Longer-Acting β_2-Specific Drugs

To avoid the adverse cardiac effects of β-adrenergic agonists, drugs have been developed that are more specific for the β_2-receptor (Table 48.1). These drugs are preferred for repeated use or long-term use. These drugs are also incorporated in some of the metered-dose inhalers used to treat bronchoconstriction.

Terbutaline (Brethine®, Bricanyl®)

Terbutaline is similar to isoproterenol for its β_2 activity, but it is longer acting (6 to 8 hours). It may be injected subcutaneously to relieve an acute episode of bronchoconstriction. (The dose in people is approximately 3.5 μg/kg, repeated once per hour.) The oral dose is 2.5 mg/dog q 8 h for dogs, and 0.625 mg (one-quarter of a 2.5-mg tablet) q 12 h for cats (e.g., cats with feline "asthma") (Hawkins and Papich, 2014). It is available as 2.5 and 5-mg tablets and 0.8 mg/ml (820 μ/ml) injection. The injection can be helpful for treatment of acute bronchoconstriction. The dose for injection in cats is 0.01 mg/kg IV or IM. Terbutaline has been used in horses to treat recurrent airway obstruction (RAO), which is a bronchoconstrictive disease in horses analogous to asthma in people. It is not absorbed after oral administration in horses; therefore, injectable preparations must be used.

Metaproterenol (Alupent®, Metaprel®)

Metaproterenol is similar to terbutaline, but the duration of action is shorter (4 hours). It is available as 10 and 20-mg tablets and 2 mg/ml oral syrup. The dose in small animals is 0.325 to 0.65 mg/kg.

Albuterol (Salbutamol) (Proventil®, Ventolin®)

Albuterol is similar to terbutaline and metaproterenol in its action. Doses used in small animals are 20–50 μg/kg up to four times per day. (Dose in people is 100–200 μg/kg four times daily.) It is available as 2, 4, and 5-mg tablets and 2 mg/5 ml syrup. Levalbuterol is the R-isomer of albuterol, and is used in some products. The proposed benefit of administration of levalbuterol compared to the R-, S-racemic mixture of albuterol is that the S-form may have bronchoconstrictive and proinflammatory properties, and a pure R-isomer avoids these problems (Reinero et al., 2009). In cats, the regular use of the racemic form (R and S) of albuterol increased airway inflammation. Therefore, these authors and others have questioned the regular use of racemic albuterol in cats for treating feline asthma (Reinero, 2011; Trzil and Reinero, 2014). On the other hand, in a study in horses, administration of levalbuterol to horses with RAO did not result in greater bronchodilation compared to albuterol (Arroyo et al., 2016). Levalbuterol was an effective bronchodilator in these horses, but the short duration of action is impractical for long-term treatment of RAO.

Clenbuterol (Ventipulmin®)

Clenbuterol was approved by the FDA in 1998 for use in horses. Its use in food animals is illegal, which is discussed in the section on prohibited drugs in food producing animals. Its use has not been reported in small animals. Clenbuterol has been used primarily for the treatment of recurrent airway obstruction (RAO) (Box 48.1) in horses and some studies have demonstrated efficacy (Shapland et al., 1981). However, its bronchodilating ability has been questioned. Compared to other β agonists, such as terbutaline, clenbuterol has lower clinical efficacy because it is only a partial agonist and has lower intrinsic activity (Törneke et al., 1998; Derksen et al., 1987).

Box 48.1 Airway diseases in horses: recurrent airway obstruction (RAO) and inflammatory airway disease (IAD). Source: Data from Ivester and Couëtil, 2014; Couëtil et al., 2016; Mazan, 2015; Pirie, 2014

Formerly called chronic obstructive airway disease (COPD).
Characterized by:

- chronic airway inflammation
- labored breathing
- bronchospasm
- mucus plugs
- tissue remodeling in airways
- neutrophilic inflammation in airways
- bronchial hyperresponsiveness.

Treatments:

- environmental control
- bronchodilators (β_2 agonists)
- corticosteroids
- inhalant medications
- cromoglycate
- phosphodiesterase inhibitors.

Clenbuterol is available as a syrup (Ventipulmin® syrup, 100 ml and 33 ml bottles, 72.5 μg/ml) for horses for oral administration. The dose is 0.8 μg/kg twice daily, but can be increased to 2×, 3×, and then 4× (up to 3.2 μg/kg) if the initial dose is not effective. The duration of effect is 6–8 hours. Prolonged administration is discouraged (Mazan, 2015; Ivester and Couëtil, 2014). Prolonged administration can diminish the effect through receptor tolerance or tachyphylaxis (desensitization of receptors) (Read et al., 2012). Adverse effects in horses include sweating, muscle tremor, restlessness, and tachycardia.

Effect on exercise in horses: There is conflicting evidence on the effect of clenbuterol on exercise and muscle physiology in horses. One study indicated no improvement in aerobic metabolism of horses (Ferraz et al., 2007). On the other hand, it may have a negative ergonomic effect due to decrease in aerobic capacity, time to fatigue, cardiac function, and oxygen consumption. It has an anabolic effect on skeletal muscle but the anabolic effects do not produce greater athletic performance. One study showed that less than 2 weeks of treatment at approved doses did not reveal any adverse effects on equine cardiac or skeletal muscle (Thompson et al., 2012), but a study in rats (Huang et al., 2000) showed that down-regulation of β_2 receptors occurs after 10 days of treatment and results in a decrease in receptor expression in skeletal muscle (35% decrease) and lung (45%). It appears that the effects on equine performance may be controversial, but there is agreement among equine specialists that clenbuterol should not be used solely to enhance athletic performance (Carlos and Davis, 2007).

Prohibition to use in food-producing animals: Clenbuterol is banned from use in food-producing animals, but has been used in livestock illegally as a repartitioning agent. These agents repartition nutrients away from adipose tissue in favor of muscle (Peters, 1989). The repartitioning and anabolic effects are caused by leptin- and adiponectin-mediated effects that produce an increase in muscle mass (Kearns et al., 2006). In food animals, the result is increased carcass weight and an increased ratio of muscle to fat, while reducing the feed required per kg of weight gain. A review of the use of β-adrenergic agonists as growth-promoting agents is discussed in the article by Mersmann (1998).

Clenbuterol residues in food products pose a threat to people (e.g., pregnant women and people with heart conditions). Deaths in humans have been reported as a result of eating beef liver contaminated with clenbuterol residue, making the illegal use of clenbuterol in food animals a regulatory concern to the FDA and other international agencies. The US FDA has established a “zero tolerance” for residues (Chapter 52). In the USA, clenbuterol residues have been highest in competition "show animals". Another unapproved use of clenbuterol is the abuse by people. It is used (abused) for “muscle building” in human athletes and for weight loss. Also called “*Clen*”, it can be found widely on the internet, promoted for use in people for weight loss and muscle development.

Other β agonists used for weight gain: Zilpaterol (Zilmax®) is another β agonist that has been used in cattle. This is an FDA-approved feed supplement for cattle that has been used by cattle farmers globally for nearly two decades to improve cattle’s natural ability to convert feed into lean beef. Zilpaterol is fed at 6.8 grams per ton (90% dry matter basis) for the last 20 days on the sole ration of feed to provide 60 to 90 mg zilpaterol hydrochloride per head per day. There is a 3-day slaughter withdrawal time. In August 2013, the manufacturer withdrew the medication because of concerns about adverse effects in cattle that included difficulty walking, abnormal gait, and hip pain. Animal welfare concerns were publicized and the company withdrew the medication with plans to reintroduce at a later time.

Salmeterol and Formoterol

These drugs are long-acting β agonists that have been used in human medicine, but their use in veterinary medicine has not been reported.

Inhalant Formulations: Nebulized β Agonists

Inhaled aerosols of β_2 agonists are important drugs for treatment of acute bronchospasm in human patients with asthma or allergic bronchitis. Nebulization is the process of creating small droplets of a drug that can be inhaled into the airways. Nebulized agents are delivered via jet nebulizers, ultrasonic nebulizers, and metered-dose inhalers. (Inhalation products are also discussed with the corticosteroids in Section Inhaled Corticosteroids.) Several metered-dose inhalers are marketed for this use in people, such as albuterol (Ventolin®), bitolterol (Tornalate®), terbutaline (Brethaire®), and pirbuterol (Maxair®).

The use of these aerosols has become more common in animals because adapters are available to allow for use by animal owners. In horses, masks are available that allow a metered-dose inhaler to be used (Derksen et al., 1996; Tesarowski et al., 1994). These devices are available for dogs, cats, and horses. For example, the AeroKat® chamber has also been used to deliver these medications to cats.

Albuterol (Torpex®)

In 2002, albuterol sulfate was approved by the US-FDA for horses, indicated for relief of bronchospasm and bronchoconstriction associated with recurrent airway obstruction (RAO). It is an aerosol formulation in a pressurized canister delivered via a specialized nasal delivery bulb. The nasal bulb is inserted into the horse’s nostril and when the horse inhales, the device is activated.

Masks that fit over the horse's nose (discussed in Section Inhalant Formulations: Nebulized β Agonists) also have been used. In horses, doses of 360 or 720 μg delivered by aerosolization caused significant bronchodilation (Derksen et al., 1999). The same author also administered pirbuterol at 600 μg/horse with good results.

For small animals, the metered dose inhaler to deliver albuterol in people has been adapted for use. However, the use of inhaled albuterol in cats with hyperresponsive airway disease is discouraged because it may exacerbate airway inflammation (Reinero, 2011).

Adverse Effects from β Agonists

The most common adverse effects from β agonists involve the cardiovascular system (tachycardia) and skeletal muscles (muscle tremors) (Fox and Papich, 1989). Cardiac effects (rapid heart rate, palpitations, tremors) can be prominent with β_1 agonists and can be produced by β_2 agonists at high doses. When high doses of β agonists have been nebulized to horses, muscle twitching, sweating, and excitement have occurred. β_2-receptor agonists also inhibit uterine motility and should not be used late in pregnancy. However, these drugs have been used therapeutically for this purpose in situations in which it may be desirable to inhibit uterine contractions to delay labor. High doses of β_2 agonists also can produce hypokalemia.

As noted above in the clenbuterol section, these drugs also have properties that affect skeletal muscle. These drugs have been abused in humans and animals for their muscle-building properties. High doses can cause muscle twitching and hyperthermia.

Tolerance with Chronic Use

Regular administration of β agonists can produce drug tolerance, which is a loss in the sensitivity of β-adrenergic receptors owing to down-regulation of receptors. This effect occurs when β-adrenergic drugs are administered regularly for several weeks. Therefore, it is best to rely on these drugs intermittently and allow drug-free breaks in treatment. In animals, the best use of these drugs is for short-term treatment for acute exacerbations of bronchoconstriction and corticosteroids can be used to decrease inflammation for long-term management.

Cromolyn (Sodium Cromoglycate) (Intal®)

Cromoglycate is used occasionally to stabilize mast cells in animals with hypersensitive airways. It is usually administered as a 2% solution for nebulization in the treatment of bronchoconstrictive diseases. It has been used in people to treat asthma and occasionally nebulized to horses via a special mask to treat recurrent airway obstruction (RAO).

Mechanism of Action

Cromolyn inhibits mast cell release of histamine, leukotrienes, and other substances from sensitized mast cells that cause hypersensitivity reactions, probably by interfering with calcium transport across the mast cell membrane. It has no intrinsic bronchodilator action.

Clinical Use

Cromolyn has been used as an aerosol for treating recurrent airway obstruction (RAO) in horses (Thomson and McPherson, 1981) and has improved some clinical measurements in horses with respiratory disease (Hare et al., 1994). It has been administered via inhalation once daily for 1–4 days, which will provide a therapeutic effect for several days. In one report, nebulization of 80 mg once daily for 1–4 days prevented signs of heaves in horses for up to 3 weeks. The recommended dose is 80 mg of a 0.02% solution from an ultrasonic nebulizer, or 200 mg from a jet nebulizer (Couëtil et al., 2016). However, other studies have produced conflicting results. The primary drawback is the route of administration and timing. To be effective, it *must* be administered before the horse is exposed to the allergen (prophylactically). This agent has its effects primarily on mast cells (Hare et al., 1994). Because airway diseases in animals may have neutrophilic or eosinophilic inflammation, this treatment may have limited impact unless mast cells contribute substantially to the disease.

Nedocromil Sodium

Nedocromil sodium (Tilade) is a chemically unrelated drug, but has an antiinflammatory effect via a similar mechanism to chromolyn. It is approved for use in treating asthma in people but use in veterinary patients has not been reported.

Methylxanthines (Xanthines)

The methylxanthines include theobromine, caffeine, and theophylline. Pentoxifylline also is a methylxanthine, but is used for conditions other than asthma. The methylathines – particularly theophylline – have been used as bronchodilators, but the use is no longer common. Once a mainstay in the therapy of human asthma, theophylline use has diminished because of a high incidence of side effects in people and because there are better-tolerated and more effective drugs available. However, occasionally in small animals theophylline is used because it is tolerated well and oral dosing is convenient. There is occasional use of theophylline in horses (and pentoxifylline for other diseases), but the use of theophylline in horses is hampered by adverse effects and racing restrictions. There are no clinical studies that have documented efficacy in small animals; the use is purely anecdotal and doses based on pharmacokinetic studies.

Pharmacological Effects

The methylxanthines are classified as CNS stimulants, but they have a variety of pharmacological effects on various organ systems (Weinberger and Hendeles, 1996). The methylxanthines relax bronchial smooth muscle and produce antiinflammatory effects that are unrelated to the bronchodilating properties. In addition, there are nonrespiratory effects of methylxanthines, which include CNS stimulation, urinary diuresis (mild), as well as cardiac stimulation (mild).

Cellular Basis of Action

The cellular basis of action of the methylxanthines is still not completely understood. The effect reported in the literature is the action to inhibit phosphodiesterase types 3 and 4 (PDE-3, PDE-4). Phosphodiesterase is the enzyme that catalyzes cyclic-AMP to inactive products. Inhibition of the phosphodiesterase enzyme increases intracellular concentrations of the cyclic nucleotide cAMP. Cyclic-AMP inhibits the release of inflammatory mediators from mast cells, has antiinflammatory effects, and produces bronchial smooth muscle relaxation (Barnes, 2003).

Another mechanism of action that may explain the benefits for respiratory disease is via antagonism of *adenosine* receptors. Adenosine causes bronchoconstriction in asthmatic patients, but blocking this receptor also may contribute to the adverse effects.

Antiinflammatory Effects

The antiinflammatory effects of theophylline may occur separately – and at lower concentrations – than the bronchodilating effects (Barnes, 2003). This may occur by decreasing the expression of inflammatory genes. Treatment with theophylline has induced a decreased response to histamine and other inflammatory mediators in the airways. Theophylline's antiinflammatory effects include diminished activity of inflammatory and immune cells – especially eosinophils – in the airways. Eosinophils can play an important role in the bronchial response to inhaled allergens, and they release inflammatory mediators that induce bronchoconstriction and inflammatory changes in the airways.

Table 48.2 Formulations of theophylline

	Brand name	Percent theophylline
Theophylline base	Many	100
Theophylline elixir	Many	100
Theophylline monohydrate		90
Theophylline ethylenediamine (aminophylline)	Many	80
Choline theophyllinate (oxtriphylline)	Choledyl®	65
Theophylline sodium glycinate	Asbron®	50
Theophylline calcium salicylate	Quadrinal®	48

Formulations

Theophylline has been available in several formulations, including, injectable, aqueous solutions, elixirs, tablets, and capsules. The most convenient for small animal use are extended-release forms that allow for twice daily treatment in dogs and once-daily or once every 48 hour treatment in cats. These are discussed in more detail in Section Clinical Use in Dogs and Cats. However, the availability of these formulations has greatly declined. Because theophylline is uncommonly used in human medicine, and there are no approved veterinary formulations, products for use in animals can be difficult to locate. Examples of other forms of theophylline are presented in Table 48.2. These salts are designed to improve solubility and decrease stomach irritation. The theophylline content of these salts must be considered when calculating a dosage regimen.

Pharmacokinetics

After oral administration, theophylline is rapidly and completely absorbed. Systemic availability is 91%, 96–100%, and 100% in dogs, cats, and horses, respectively. Theophylline is metabolized primarily by the liver in all species; only 10% of the dose is eliminated unchanged in the urine. The pharmacokinetics have been studied in several veterinary species and are listed in Table 48.3 with comparisons to people.

Plasma Concentrations and Clinical Monitoring

Theophylline drug plasma assays are available in many laboratories. When theophylline is used long term, monitoring is recommended to establish the optimum dose. In dogs and cats, the accepted therapeutic plasma concentration is 10 to 20 μg/ml, but these values were extrapolated from human studies. In animals, we aim for plasma concentration greater than 10 μg/ml (usually 10–20 μg/ml) for clinical effects. Plasma concentrations greater than 15 μg/ml have been reported to cause clinical adverse effects in horses.

Table 48.3 Theophylline pharmacokinetics and doses

Species	Half-life (hours)	Volume of distribution (l/kg)	Percent absorbed orally	Suggested dose
People	6–8	0.5	90	4 mg/kg q6h
Dog	5.7	0.82	91	9 mg/kg q6–8h, or 10 mg/kg q12h of the extended release formulations
Cat	7.8,11.7 (IV) 14–18 (oral)	0.46, 0.86	96–100	4 mg/kg q8–12h or extended-release at 15 mg/kg (tab) and 19 mg/kg (cap) q24h (q48h may be possible in some cats)
Cattle	6.4	0.815	93	20 mg/kg q12h
Horse	12–15	0.85–1.02	100	5 mg/kg q12h

Antiinflammatory action may occur in patients at concentrations that are below the concentrations usually considered for bronchodilation. For example in people, a concentration of 6.6 μg/ml theophylline caused a reduction in activated eosinophils (Sullivan et al., 1994). In the review by Barnes (2003) the antiinflammatory effects are reported to occur in people at concentrations of 5–10 μg/ml, which is approximately half of the concentration needed to produce bronchodilation.

Side Effects and Adverse Effects

Mild adverse effects include gastrointestinal signs, which includes nausea and vomiting. More important adverse effects of theophylline are attributed to cardiac stimulation. In this regard, theophylline is more potent than either caffeine or theobromine. The cardiac effects may be summarized as increased heart rate, increase in myocardial contractility (mild), improved right and left systolic function, vasodilation (mild), and diuretic (weak). At high doses, cardiac arrhythmias are possible.

CNS stimulation is more likely from caffeine than theophylline or theobromine. However, at high doses, theophylline also can affect the CNS. These are reported less frequently from theophylline use in small animals than in humans, but they can be common in horses. The CNS effects can be characterized by increased alertness, agitation, nervousness, increased activity, and convulsions at high doses. At high doses there is decreased cerebral blood flow (26%), which may be related to the incidence of seizures.

Caution is advised after rapidly intravenous dosing as adverse effects have been described when theophylline is rapidly administered intravenously in horses and dogs. If the drug is administered orally, high peak plasma concentrations are less likely (Munsiff et al., 1988).

Drug Interactions

Theophylline relies on hepatic metabolism by cytochrome P450 enzymes for clearance. Therefore, interactions are possible when other drugs are administered that affect these enzyme systems. The metabolism of theophylline may be inhibited by erythromycin, fluoroquinolone antibiotics (for example, enrofloxacin), and cimetidine. The metabolism may be induced by rifampin and phenobarbital, which may necessitate increasing the dose if these drugs are used together. Activated charcoal will increase the clearance of theophylline and other methylxanthines and is useful for treatment of a toxic overdose.

Clinical Use in Dogs and Cats

Theophylline has been used for the treatment of both cardiac and respiratory diseases in dogs. Some veterinarians have included theophylline in regimens for the management of congestive heart failure, although this has become an outdated treatment because of availability of newer cardiac drugs. (Note that pimobendan and milrinone, discussed in Chapter 21, are also phosphodiesterase inhibitors.) Theophylline is also employed for the management of intrathoracic collapsing trachea and various forms of bronchitis.

Older sustained-release tablets have been studied in dogs and cats (Koritz et al., 1986; Dye et al., 1989). However, these formulations were recently discontinued and the dose recommendations no longer apply. Decreased availability of older sustained-release formulations led to the use of sustained-release tablets and capsules. These have now become unavailable to many pharmacies, which has led to a decline in use. If available, oral administration of sustained-release formulations in dogs at a dose of 10 mg/kg, q 12 h will produce concentrations in dogs within a range considered to be therapeutic (Bach et al., 2004). Studies in cats (Guenther-Yenke et al., 2007), showed that a dose of 100 mg per cat of the tablet, or 125 mg/cat of the capsule (approximately 15 or 19 mg/kg, respectively) every 24–48 hours maintained plasma concentrations in a range considered to be therapeutic.

Clinical Use in Horses

Administration of theophylline to horses has a narrow therapeutic index and it is considered less effective than other agents (Box 48.1). Adverse effects have prevented more common use and, because of the CNS stimulant effect, it is banned from performance horses.

Despite the risk of adverse effects and questionable efficacy, theophylline has been considered for management of RAO in horses. Studies in the 1980s (Button et al., 1985; Errecalde et al., 1984; Ayres et al., 1985; Ingvast-Larsson et al., 1989; Kowalczyk et al., 1984) summarize the pharmacokinetics and effects of theophylline in horses. Oral doses are preferred to avoid the high concentrations from injections. A loading dose of 12 mg/kg has been followed by maintenance doses of 5 mg/kg, every 12 hours. One study demonstrated that affected horses showed decreased wheezing, decreased respiratory effort, and an improvement in $\mathrm{P}_{\mathrm{CO}_2}$ and blood pH following theophylline administration. However, none of the horses returned to normal. There also is evidence that phosphodiesterase inhibitors are not effective in horses with recurrent airway obstruction (Lavoie et al., 2006). Theophylline produces a positive cardiac chronotropic effect and a weak diuretic effect in horses. Toxicosis can occur from large doses and doses administrated rapidly intravenously. Toxic signs include tremors, excitement, tachycardia, and sweating.

Clinical Use in Cattle

Although there is little clinical experience with the use of theophylline in cattle, experimental evidence suggests that it is a poor bronchodilator in this species (McKenna et al., 1989).

Anticholinergic Drugs

Anticholinergic (parasympatholytic/antimuscarinic) drugs such as atropine and glycopyrrolate are effective bronchodilators and N-butylscopolammonium bromide (*Buscopan* injectable solution) has emerged as an effective agent for horses. (The pharmacology of anticholinergic agents was provided in more detail in Chapter 8.) Cholinergic stimulation causes bronchoconstriction. Anticholinergic drugs inhibit vagal-mediated cholinergic smooth muscle tone in the respiratory tract because asthmatic individuals have excessive stimulation of cholinergic receptors. In some people, COPD can be more effectively treated with anticholinergic drugs than by β agonists (Barnes, 2000). Although atropine will provide relief from these effects in many patients, the side effects are unacceptable for long-term use. Adverse effects involve the CNS and gastrointestinal systems.

Use of Anticholinergic Drugs in Horses

Pearson and Riebold (1989) compared the effects of atropine, isoproterenol, and theophylline in horses with RAO (Box 48.1). Atropine at doses of 0.02 mg/kg, IV was better at relieving some signs of RAO (reduction in intrathoracic pressure for example) than either theophylline or isoproterenol. Isoproterenol was more effective in this study than theophylline.

Drug Choices

If anticholinergic drugs are administered, the quaternary amines such as glycopyrrolate (Robinul-V®), propantheline, (ProBanthine®), and isopropamide should be used instead of atropine because quaternary amines are less likely to cross the blood–brain barrier and CNS side effects will be minimized. (This property is discussed in Chapter 46.)

Atropine is acceptable for short-term use and a 5 mg IV dose has been used as a response test in horses suspected of presenting with RAO. Ipratropium bromide (Atrovent®) is a quaternary amine that is an effective bronchodilator in human asthmatic patients. It is administered as an aerosol and is the first anticholinergic drug to be approved as a bronchodilator. Since ipratropium is not absorbed from the airways, it is described as a "topical form of atropine." It has been administered to horses for treatment of RAO and produced effects for 6 hours at a dose of 2 μg/kg.

N-butylscopolammonium bromide (Buscopan® injectable solution)**:** This anticholinergic, antimuscarinic agent is a quaternary ammonium compound approved by the FDA for treatment of some forms of colic in horses (discussed in Chapter 46). Adverse effects include transient tachycardia and decreased intestinal motility. Because of its antimuscarinic action, it has been administered to horses with RAO at a dose of 0.3 mg/kg IV as a single dose. It has a rapid onset (within 2 minutes) and has a short duration of action that inhibits intestinal motility for only 2 hours (Couëtil et al., 2012).

Adverse Effects

The cardiac effects and inhibition of gastrointestinal function prohibit long-term use of atropine. The topical drugs (e.g., ipratropium) have less systemic effects. Because these agents are used in horses, the most important concern is the effect on intestinal motility. Atropine should not be used repeatedly in horses because it can cause ileus. N-butylscopolammonium bromide has become preferred for the acute treatment of bronchoconstriction in horses because when administered once (0.3 mg/kg IV), it was shorter acting, and produced fewer adverse effects, including those on the heart and intestine, than atropine (de Lagarde et al., 2014).

Glucocorticoids

Glucocorticoids decrease inflammation associated with inflammatory pulmonary diseases. Prednisolone has been effective for treatment of feline tracheobronchitis ("feline asthma"), nonseptic pulmonary diseases associated with pulmonary infiltrates of leukocytes (noninfectious bronchitis), allergic bronchitis, and recurrent airway obstruction (RAO) and inflammatory airway disease (IAD) of horses. For treatment of asthma in people, inhaled corticosteroids are recognized as the most effective therapy available (Barnes, 1995b, 2006). In one article, they were called the "drugs to beat" (Barnes, 2006), and have become the mainstay of asthma management for people.

Mechanism of Action

The pharmacology of the glucocorticoids was discussed in more detail in Chapter 29, with some of the immunosuppressive properties discussed in Chapter 45. In patients with inflammatory airway diseases, glucocorticoids have potent antiinflammatory effects on the bronchial mucosa. Glucocorticoids bind to receptors on cells and inhibit the transcription of genes for the production of mediators (cytokines, chemokines, adhesion molecules) involved in airway inflammation (Rhen and Cidlowski, 2005). In horses with RAO, administration of oral dexamethasone in combination with feeding changes decreased the gene expression of proinflammatory cytokines in bronchoalveolar cells (DeLuca et al., 2008). A decrease in the synthesis of inflammatory mediators such as prostaglandins, leukotrienes, and platelet-activating factor caused by glucocorticoids also may be important (Barnes, 1995a, 1989, 2006). Glucocorticoids have a more pronounced effect on neutrophils and eosinophils than mast cells, which is important because neutrophilic and eosinophilic inflammation has been cited as an important component of equine and feline airway disease (Reinero, 2011; Trzil and Reinero, 2014; Mazan, 2015; Couëtil et al., 2016; Pirie, 2014). Glucocorticoids also enhance the action of adrenergic agonists on β_2 receptors in the bronchial smooth muscle, either by modifying the receptor or augmenting muscle relaxation after a receptor has been bound. Corticosteroids may prevent down-regulation of β_2 receptors. Glucocorticoids and theophylline used together appear to be synergistic (Barnes, 2003).

Clinical Use

Dogs

Oral prednisolone or prednisone is usually the drug of choice when a corticosteroid is needed for treating chronic airway disease. A typical antiinflammatory dosage is 0.5–1.0 mg/kg. After an initial course of treatment many patients can be managed by administering this dose on an every-other-day (EOD) basis. Inhaled corticosteroids also can be administered, such as fluticasone delivered with a metered-dose inhaler (for example, 110 μg twice daily). The inhaled agents are discussed in Section Inhaled Corticosteroids.

Cats

Because cats are somewhat resistant to glucocorticoids, higher doses have been used compared to doses administered to dogs. Oral prednisolone initial dosages of 2–4 mg/kg/day have been used for 10–14 days, followed by chronic doses of 1.0 mg/kg/day for the treatment of feline asthma (Box 48.2). For cats, prednisolone should be used instead of prednisone because of an absorption/conversion problem similar to horses (see Section Horses) (Graham-Mize and Rosser, 2004). For difficult to medicate cats, some veterinarians have administered 20 mg per cat of a long-acting formulation, methylprednisolone acetate (Depo Medrol®) intramuscularly. The effects of one injection may persist for 3 weeks.

Box 48.2 Treatment options for feline asthma

Corticosteroids:

- Prednisolone 1–2 mg/kg q 12 h initially, then taper to lower dose
- Methylprednisolone acetate (Depo Medrol) 10–20 mg IM every 4–8 weeks
- Metered-dose inhaler (e.g., fluticasone at a dose of 44 μg per puff q 12 h).

β agonists (for acute treatment):

- Terbutaline
- Albuterol.

Methylxanthines:

- Theophylline
- Aminophylline.

Adverse effects in cats are a concern with long-term treatment (Box 48.3). Among the concerns are that corticosteroids may exacerbate or increase the risk of congestive heart failure in cats (Smith et al., 2004; Ployngam et al., 2006). The proposed mechanism for increasing this risk is increase in plasma glucose, volume expansion, and increase in plasma volume. The vascular volume increase may lead to an overload. To avoid systemic adverse effects, topical (inhaled) formulations have been used (see Section Inhaled Corticosteroids). In cats with feline asthma and risks such as heart disease or diabetes mellitus, cyclosporine may be considered as an alternative (Nafe and Leach, 2015). Use of cyclosporine in cats is discussed in more detail in Chapter 45.

Box 48.3 Possible adverse effects of corticosteroids in cats

- Behavior changes
- Increased appetite
- Weight gain
- Hyperglycemia, and increased risk of diabetes mellitus
- Increased plasma volume (secondary to hyperglycemia)
- Increased risk of heart disease (secondary to increase in plasma volume)
- Hepatomegaly

Horses

In horses, corticosteroids are important for management of recurrent airway obstruction (RAO) and inflammatory airway disease (IAD) in addition to environmental control and other measures (Box 48.1). Both prednisolone and dexamethasone, when combined with environmental control, had beneficial effects on heaves score, blood gases, and endoscopic scores (Courouce-Malblanc et al., 2008). Even with continuous antigen exposure, oral prednisolone and dexamethasone improved pulmonary function in horses with airway obstruction (Leclere et al., 2010). Inhaled corticosteroids delivered by metered-dose inhalers (discussed in Section Inhaled Corticosteroids) are more expensive but have been used to minimize the risk of systemic adverse effects.

Although oral corticosteroids are used in horses, there are no convenient dose formulations developed specifically for horses. In some cases tablets have been crushed and added to a drug vehicle or mixed with feed (grain). In horses, one should be cognizant of the dose form administered. Prednisone in horses is either not absorbed and/or not converted to the active prednisolone after absorption (Peroni et al., 2002). Therefore, prednisolone tablets are the preferred drug for oral administration. The dose used initially is approximately 2 mg/kg oral, once a day then tapered to 1 mg/kg. Oral dexamethasone is absorbed orally in horses and also can be used. It has been added to the horse's feed or mixed with a paste. The typical oral dose of dexamethasone is 0.1–0.05 mg/kg once per day then tapered to the lowest effective dose. In a study in which dexamethasone was effective for decreasing inflammatory cytokine expression in RAO horses, a decreasing oral dexamethasone dose of 0.165 mg/kg per day to 0.04 mg/kg per day over a course of 21 days was used (DeLuca et al., 2008).

Injections of dexamethasone have quickly improved clinical signs of airway obstruction when administered at doses of 0.1 mg/kg (Rush et al., 1998). Dexamethasone by injection was more effective than inhaled corticosteroids in that study. In other studies (Leclere et al., 2010; Courouce-Malblanc et al., 2008) dexamethasone was more effective than oral prednisolone for improving pulmonary function and bronchioalveolar lavage (BAL) cytology. An FDA-approved drug for horses is the suspension of dexamethasone 21-isonicotinate (Voren). It is administered at a dose of 0.06 mg/kg, and up to 0.1 mg/kg IM (not intended for IV use), then tapered to 0.02–0.05 mg/kg once daily, or every other day. Some of the cited studies demonstrate decreased inflammation in respiratory fluids. However, in one study, there was clinical improvement but no effect on BAL fluid cytology or NF-κB and AP-1 activity (Couëtil et al., 2006). Therefore, there may be improvements in pulmonary function in RAO, but are not always accompanied by a decrease in airway inflammatory cells or a suppression of inflammatory cytokines. Nevertheless, there is agreement among equine experts that the best results are obtained when corticosteroids administration is combined with environmental control (Couëtil et al., 2016; Ivester and Couëtil, 2014; Mazan, 2015). There is a concern that repeated use of injections of corticosteroids in horses may result in adverse effects, such as adrenal suppression, signs of hyperadrenocorticism, and laminitis, *although proof of corticosteroid-induced laminitis is inconclusive* (Robinson et al., 2009). Inhaled corticosteroids may minimize the risks of adverse effects (see Section Inhaled Corticosteroids).

Inhaled Corticosteroids

Glucocorticoids are among the most valuable drugs for managing asthma in people. For people, a metered-dose inhaler is used to deliver the drug topically in order to avoid systemic adverse effects (Derendorf et al., 2002). According to one review, inhaled corticosteroids are the most effective agents available for the symptomatic control of asthma and improvement in pulmonary function (Busse and Lemanske, 2001). Examples of aerosolized corticosteroids are listed in Table 48.4 and include beclomethasone (Beclovent®), flunisolide (Aerobid®), fluticasone (Flovent®), triamcinolone (Azmacort®), and budesonide (Pulmicort®). Fluticasone is the most potent (18 × dexamethasone) and is usually the one used in

Table 48.4 Examples of corticosteroids available as metered-dose inhalers

Drug	Brand name	Dose Delivered
Beclomethasone dipropionate	Vanceril®	40 or 80 µg per puff
Budesonide	Pulmicort®	200 µg per puff (dry powder)
Flunisolide	Aerobid®	250 µg per puff
Fluticasone propionate (most potent)	Flovent®	44, 110, or 220 µg per puff
Triamcinolone acetonide	Azmacort®	100 µg per puff

veterinary medicine (Table 48.4). In people it has a systemic absorption of only 18–26%, but there are extensive first-pass effects and high plasma protein binding preventing activity of systemic blood concentrations if it is swallowed after delivery. Therefore, the systemic action and adverse effects are minimized, even though some adrenal suppression can be detected. Suppression of the hypothalamic–pituitary–adrenal axis can still be observed in animal studies because this is a very sensitive measurement of systemic exposure.

Use in Horses

The metered-dose inhalers designed for people can be used in horses with the aid of an equine-adapted handheld metered-dose delivery device (Derksen et al., 1996; Rush et al., 2000). Delivery devices used in horses include the AeroHippus® mask (Trudell Medical International). One of the limitations for the use is the expense of the metered-dose inhaler products; however, when cost is not a factor these agents have been effective and the use supported by equine medicine experts (Couëtil et al., 2016; Ivester and Couëtil, 2014; Mazan, 2015; Pirie, 2014) (Box 48.1).

There is convincing evidence that aerosolized corticosteroids improve clinical signs and pulmonary function, but effects on other factors can be inconsistent and dependent on the study design and whether or not there was accompanying measures to control the environment. Aerosolized beclomethasone dipropionate using an equine-adapted metered dose inhalation was effective for reducing airway inflammation in horses with RAO (Rush et al., 1998, 2000). Horses responded within 24 hours. Administration of 500 μg every 12 hours to horses produced less adrenal suppression than larger doses and still provided beneficial effects. Administration of 500 μg of beclomethasone every 12 hours for 10 days improved pulmonary function in horses with RAO, but did not change bronchoalveolar lavage fluid cytology or cytokine activity (Couëtil et al., 2006). In this study, the effects of inhaled beclomethasone on pulmonary function were not accompanied by a decrease in airway inflammation or suppression of transcription factors NF-κB and AP-1.

Fluticasone also is frequently used (Table 48.4). Fluticasone treatment to horses with heaves produced resolution of clinical signs, normalization of pulmonary function, and significant decrease in BAL neutrophilia. There was also a significant decrease in inflammatory cytokine expression (Giguère et al., 2002). When administered at a dose of 6,000 μg every 12 hours it was as effective as dexamethasone for prevention of acute exacerbations of RAO, but not as effective for treatment as for prevention (Robinson et al., 2009). Fluticasone (2,000 μg twice daily initially then 2,000 μg once a day) produced significant improvement in clinical signs and lung function and no significant adverse effect on innate and acquired humoral and cell-mediated immune parameters (Dauvillier et al., 2011). Currently recommended doses are betamethasone 1–8 μg/kg every 12 hours or fluticasone 1–6 μg/kg every 12 hours (Couëtil et al., 2016).

Use in Small Animals

Metered-dose inhalers have also been successfully used in small animals, and are an accepted treatment for feline asthma (Trzil and Reinero, 2014; Reinero, 2011) (Box 48.2). For this use, the AeroKat® chamber described earlier has been used to deliver the drug. Budesonide or fluticasone are most often administered because of their high potency (Table 48.4) and low systemic effects. A typical dose for fluticasone for a cat is 110 μg (one puff from a 110 μg metered dose inhaler) per day. Higher-dose inhalers that deliver 220 μg are also available, but in one study in cats (Cohn et al., 2008) three fluticasone doses (44, 110, and 220 μg per cat) twice daily via metered dose inhaler were equivalent in an experimental model of feline asthma.

In one study, inhaled fluticasone reduced bronchial hyperresponsiveness and bronchoconstriction in cats with bronchitis at a dose of 250 μg per cat daily (Kirschuink et al., 2006). This dose also decreased inflammatory cells and prostaglandins in bronchoalveolar lavage fluid. When asthmatic cats are administered inhaled corticosteroids twice a day and allowed five to seven breaths (10 seconds) from the chamber, it reduces the need for oral prednisolone. In cats, flunisolide was studied for its systemic effects after administration by inhalation (Reinero et al., 2006). Although there was some suppression of the hypothalamic–pituitary–adrenal axis (indicating some systemic absorption), systemic effects on immune cells (lymphocytes and lymphocyte function) were not observed, which demonstrated that inhaled flunisolide is capable of producing a local effect in the airways, but with minimal effects on the systemic immune system.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) have been administered for some types of pulmonary disease. The drug most often investigated has been flunixin meglumine. It is registered for cattle to treat inflammatory respiratory problems and as an adjunct treatment of bovine respiratory disease (BRD) and is included in one of the antibiotic combinations used to treat BRD (flunixin meglumine and florfenicol in Resflor Gold®).

Diseases in which NSAIDs may have a benefit include pulmonary thromboembolism (for which antiplatelet doses of aspirin are used), pulmonary effects from endotoxin in horses and dogs (for which flunixin meglumine has been used), and in cattle with BRD, and pulmonary disease from PI-3 and 3-methyl indole in cattle.

Leukotriene Inhibitors

Leukotrienes, such as LTD_4 contribute to airway inflammation by increasing migration of eosinophils, producing bronchoconstriction, and increasing airway wall edema. Inhibitors or blockers of leukotrienes have been used to treat these airway diseases. These were discussed in more detail by Drazen et al. (1999) and reviewed by Werz and Steinhilber (2006) and Peters-Golden and Henderson (2007). The leukotrienes have not been demonstrated to be important mediators in feline asthma (Norris et al., 2003). Therefore, these inhibitors may not have a role in feline respiratory disease. However, there is evidence that LTB_4 – rather than the other leukotrienes – may contribute to airway inflammation in horses with recurrent airway obstruction (RAO) (Lindberg et al., 2004). An experimental 5-lipoxygenase inhibitor (fenleuton) – which decreases LTB_4– produced improvement in horses with RAO (Marr et al., 1998), but an LTD_4 receptor antagonist did not (Lavoie et al., 2002).

Lipooxygenase Inhibitor: Zileuton (Zyflo®)

Zileuton is an oral drug for treating asthma in people. It inhibits the enzyme 5-lipoxygenase and thereby inhibits synthesis of inflammatory leukotrienes. This drug has broader actions than the leukotriene receptor blockers because it inhibits effects of both LTB_4 and the cysteinyl leukotrienes (LTC_4, LTD_4, LTE_4). However, it has been less effective than leukotriene receptor blockers (see Section Leukotriene Receptor Blockers) because, at the doses administered, it does not achieve complete suppression of the 5-lipoxygenase enzyme. In people, the safety profile has not been as good as the receptor blockers. The effectiveness of zileuton for respiratory diseases in animals has not been reported. For people the dose is 600 mg, q 6 h and this dose has been extrapolated to animals for some studies. Treatment of other diseases in animals (e.g., allergic skin disease) have been investigated, but it has not been effective. In people it has been associated with hepatitis in some individuals.

Leukotriene Receptor Blockers

Zafirlukast (Accolate®), pranlukast, and montelukast (Singulair®) are leukotriene receptor blockers that have been used as oral drugs for treating asthma. They block the cysteinyl leukotriene receptor, therefore blocking the effects of LTC_4, LTD_4, and LTE_4– primarily at the $CysLT_1$ receptor site – but these drugs do not block receptors for the leukotriene LTB_4 (Drazen et al., 1999). The $CysLT_1$ receptor mediates sustained bronchoconstriction, mucus secretion, and edema in the airways (Peters-Golden and Henderson, 2007). These drugs have been generally well tolerated in people, but there are some drug interactions with zafirlukast (inhibition of CYP-450 enzymes). Montelukast has fewer adverse effects in people and less risk of drug interaction than zafirlukast. The use of these drugs has not been reported to be effective for treating respiratory diseases in animals. Doses in animals are not established, but the dose in people for zafirlukast is 20 mg/person twice daily and for montelukast it is 5 mg for children and 10 mg for adults.

Expectorants and Mucolytic Drugs

The expectorants and mucolytics comprise a diverse group of compounds, with many proposed benefits but few clinical studies that have documented efficacy. These drugs have been used to increase the output of bronchial secretions, enhance clearance of bronchial exudate, and promote a more productive cough. Some of these drugs have a traditional use in veterinary medicine but their efficacy has not been established.

Saline Expectorants

These drugs are promoted to stimulate bronchial mucus secretions via a vagal-mediated reflex action on the gastric mucosa. Even though there are no well-designed studies that support an expectorant effect from these products, particularly the ammonium compounds, stimulating the stomach appears to trigger a reflex that stimulates bronchial secretions. However, for some of these drugs, such as potassium iodide, the dose used clinically is too low to be effective. Examples of expectorants include ammonium chloride, ammonium carbonate, potassium iodide, calcium iodide, and ethylenediamine dihydroiodide (EDDI). EDDI is the best known of these compounds by veterinarians because it is also added to the feed of cattle for the purpose of decreasing foot rot infections, lumpy jaw (*Actinomyces bovis*), woody tongue (*Actinobacillus lignieresi*), and bronchitis. There is a lack of published scientific evidence for a beneficial effect.

Direct Stimulants

Volatile oils such as eucalyptus oil (found in cough drops such as Halls Mentho-Lyptus) and oil of lemon are believed to directly increase respiratory tract secretions. Their clinical efficacy in veterinary medicine is unknown.

Guaifenesin (Glyceryl Guaiacolate) and Guaiacol

Guaifenesin compounds are typically classified as muscle relaxants in anesthesia and as anesthetic adjuncts, but they also may have an expectorant effect. The anesthetic effects are discussed in Chapter 14. Their mechanism of action is uncertain, but it is possible that these compounds stimulate bronchial secretions via vagal pathways. Although guaifenesin is contained in many OTC cough remedies, such as Robitussin®, Vicks®, and others, the efficacy is highly questionable because most preparations do not contain a large enough dose. Studies that have measured the expectorant effect of guaifenesin have noted that it does not change the volume or viscosity of bronchial secretions, but it may accelerate particle clearance from the airways.

Formulations used in people (but not evaluated in animals) employ higher doses than older OTC drugs. The higher-dose formulations for people include Mucinex® (600 and 1200 mg tablet), Mucinex-D® (with pseudoephedrine), and Mucinex-DM® (with dextromethorphan). Most typical OTC older formulations contain doses of 100 mg.

Acetylcysteine (Mucomyst®)

Acetylcysteine is available as a 10% solution that can be nebulized to patients. It is used in human patients with obstructive airway disease and children with cystic fibrosis to help clear mucus. Its mucolytic effect is caused by an interaction of the exposed sulfhydral groups on the compound with disulfide bonds on mucoprotein (Ziment, 1988). Acetylcysteine helps break down respiratory mucus, reduce the viscosity of mucus, and enhance the clearance. Acetylcysteine may also increase the levels of glutathione, which is a scavenger of oxygen-derived free radicals. In Europe this drug is also available as an oral formulation. In human pediatric patients 2–4 ml of a 10% solution of *N*-acetylcysteine is nebulized three or four times daily. However, the use of nebulized acetylcysteine is discouraged in cats because it produced adverse effects and increased airway resistance (Reinero et al., 2011).

Other uses for acetylcysteine: Acetylcysteine may also increase the levels of glutathione, which is a scavenger of oxygen-derived free radicals. This property has led to the use of acetylcysteine to treat some intoxications. The most common condition is acetaminophen (Tylenol) toxicosis in cats.

Demulcents

Many OTC preparations are formulated in an oily or syrup base to provide a demulcent action (soothing effect). They are usually used to soothe the pharynx and thus may have an antitussive effect. Home remedies such as honey mixed with herbal tea or distilled spirits probably have this effect.

Decongestants

Decongestants are used to “dry up” mucus membranes when rhinorrhea occurs (in people, caused by the common cold and allergic rhinitis). Decongestants are sympathomimetic drugs that directly stimulate the α-adrenergic receptors, and indirectly by increasing release of norepinephrine. When α-receptors are stimulated in mucus membranes, a local vasoconstriction is produced which results in a decongestant effect. Alpha-receptors are also found in many tissues of the body, including, bladder sphincter, peripheral arteries and veins, coronary vessels, and myocardium. Therefore, stimulation of these receptors can lead to the adverse cardiovascular consequences. The pharmacology of adrenergic agonists was discussed in more detail in Chapter 7.

Topical Decongestants

Short-acting topical agents include phenylephrine and phenylpropanolamine, which are common ingredients in OTC nasal sprays (e.g., NeoSynephrine®). These products also have been applied topically to decrease bleeding associated with some surgical procedures (for example, nasal turbinate surgery in horses and dogs). Some topical decongestants are particularly long acting, such as oxymetazoline (Afrin®) and xylometazoline (Dristan®). Caution should be exercised when using the topical products chronically. Rebound inflammation and hyperemia may occur when the action of the drug diminishes, resulting in a worsening of the problem. The clinical use of these agents for nasal problems is rare in animals because they are difficult and inconvenient to administer.

Systemic Decongestants

The systemic use of adrenergic agonists as decongestants has been a common practice in medicine for decades. In human medicine, OTC (nonprescription) formulations for colds and allergies have contained ephedrine, the isomer pseudoephedrine (Sudafed®), or a similar drug, phenylpropanolamine (PPA). Side effects from the orally administered drugs include vasoconstriction and increased blood pressure in susceptible individuals, and excitement. A change in heart rate is possible from direct stimulation (increased heart rate), or vasoconstriction (decreased heart rate). In dogs, PPA toxicosis is possible either from accidental exposure or therapeutic doses. These effects were described in reports of exposure in dogs (Peterson et al., 2011). Clinical signs of toxicity in dogs consisted of cardiovascular effects (tachycardia, bradycardia, and hypertension), gastrointestinal signs (vomiting, salivation, and anorexia), and CNS effects (agitation, muscle tremors, and mydriasis). There are some problems with the abuse of these agents in humans, which has limited the veterinary availability of these compounds.

The original OTC forms of phenylpropanolamine are no longer used – popular brand names were Dexatrim® and Acutrim® (appetite suppressants), and Propagest® and Rhindecon ® (decongestants). A study in 2000 suggested that phenylpropanolamine in appetite suppressants, and possibly decongestants, is a risk factor for hemorrhagic stroke in women (Kernan et al., 2000). Because of the risk of hemorrhagic stroke in women, these products have been largely removed from the human market, but there are now veterinary forms of these drugs for treating urinary incontinence (see Section Use of Decongestants for Treatment of Incontinence).

The other major concern with OTC decongestants is the diversion to manufacturing methamphetamine. Phenylpropanolamine, ephedrine, and pseudoephedrine have been used as raw ingredients to illegally manufacture methamphetamine for “street use” in the so-called “meth labs.” Pseudoephedrine closely resembles methamphetamine in structure. Because of this diversion, the quantity of pseudoephedrine (the only one currently available OTC) that one can purchase is limited by most pharmacies. In some states, pseudoephedrine may be obtained without prescription, but it must be dispensed by the pharmacists (behind the counter). Pseudoephedrine has been eliminated from all OTC medications and replaced by less effective drugs.

Use of Decongestants for Treatment of Incontinence

Although these drugs are rarely used as sinus decongestants in veterinary medicine they are popular drugs for treating incontinence in dogs. The effect of phenylpropanolamine (PPA) and other sympathetic agonists, such as pseudoephedrine, for treating urinary incontinence arises from their stimulation of the α-adrenergic receptor – to increase the tone of the urinary sphincter, and its β-adrenergic receptor effects – to relax the detrussor muscle of the bladder wall, and allow more urine filling.

The most common drug used for this purpose has been PPA (Moreau and Lappin, 1989). PPA has been tested and is FDA approved for treating incontinence in dogs. The formulations of PPA marketed for treatment of urinary incontinence in dogs include tablets and liquid forms (e.g., Proin ®chewable tablets). The dose is approximately 2 mg/kg oral, q 12 h, but may be reduced to 1 mg/kg or administered less frequently in some dogs.

Respiratory Stimulants

Doxapram stimulates respiration by direct stimulation of the medullary respiratory center and activation of the aortic and carotid body chemoreceptors to improve sensitivity to carbon dioxide. These receptors are sensitive to changes in carbon dioxide, which in turn stimulate the respiratory center. Doxapram (Dopram®) is used primarily in emergencies, during anesthesia, or to decrease the respiratory depressant effects of certain drugs (e.g., opiates, barbiturates).

The primary use of doxapram in horses is for the treatment of respiratory acidosis in foals. The syndrome of hypoxic–ischemic encephalopathy (perinatal asphyxia or neonatal maladjustment syndrome) is common in neonatal foals. Doxapram has been administered as an initial IV dose of 0.5 mg/kg, followed by a constant rate infusion of 0.03 or 0.08 mg/kg/min for 20 minutes (Giguère et al., 2007). This administration has restored normal ventilation, improved blood pH, Pao_2, and respiratory rate in neonatal foals in a dose-dependent manner. In a clinical study by the same investigators (Giguère et al., 2008) a dose of 0.02–0.05 mg/kg/min constant rate infusion in foals with respiratory acidosis caused by neonatal maladjustment syndrome improved respiratory rate ventilation and $Paco_2$. Doxapram has also been administered to neonatal foals as a stimulant to increase their suckling activity shortly after birth and subsequently decrease the incidence of failure of passive transfer of immunoglobulins.

Ophthalmic Pharmacology

Alison Clode

Pertinent Ocular Anatomy and Physiology

The ocular globe is housed within the orbit and protected by the bony and soft tissue components of the orbit, as well as the adnexal structures. The adnexal support tissues of the eye include the eyelids, nictitating membrane, conjunctiva, lacrimal glands, and nasolacrimal system, all of which serve various functions, such as mechanical protection (i.e., blinking and tearing from the eyelids), and immune surveillance (i.e., immune cells within the conjunctiva). The globe itself is composed of three tunics: the external, fibrous tunic (cornea and sclera), which provide rigidity as well as focusing ability; the middle vascular tunic (uveal tract = iris + ciliary body + choroid), which provide blood supply to the globe, maintain the intraocular pressure (IOP), and control light entry to the retina; and the neural tunic (sensory retina), which provides signal transmission requisite for visual function. The crystalline lens focuses light rays on the sensory retina, providing optimal focusing power for visual clarity. Aqueous humor (AH) produced by the ciliary body occupies the space between the cornea and the lens (anterior chamber), and nourishes the avascular and transparent cornea and lens. Vitreous humor (VH) occupies the space between the lens and sensory retina, and maintains structural integrity of the posterior portion of the globe. The globe may also be subdivided into the anterior segment (structures anterior to the junction of the retina and ciliary body), and posterior segment (structures posterior to this junction), a distinction important in consideration of ocular drug delivery and penetration.

Two blood–ocular barriers, the blood–aqueous and blood–retinal barriers, limit the entrance of blood components, such as large proteins, white blood cells, red blood cells, and lipid, into the eye, thus maintaining transparency of the ocular media necessary for vision. While effective at maintaining ocular clarity, these barriers also impede entrance of many drugs into the eye, thus potentially diminishing therapeutic effectiveness. Importantly however, intraocular inflammation, as is commonly present in ocular diseases necessitating pharmacotherapy, decreases effectiveness of the blood–ocular barriers, enabling some drugs to enter the eye.

Autonomic ocular innervation is both parasympathetic and sympathetic, with acetylcholine and norepinephrine, respectively, serving as the postganglionic neurotransmitters of the two systems. Most notable in the context of ocular pharmacotherapy is parasympathetic innervation of the lacrimal glands, iris sphincter muscle, and extraocular muscles, and sympathetic innervation of the adnexal and orbital smooth muscle and iris dilator muscle. Alpha- and beta-adrenergic receptors are also present on the ciliary body (where AH is produced) and iridocorneal angle (ICA) structures (where AH drains), thus impacting maintenance, and potential therapy, of IOP.

Factors Influencing Drug Levels in Ocular Tissues

Ocular Factors

Multiple barriers to drug penetration exist, which are inherent to ocular structures regardless of route by which drugs are administered.

Anteriorly, the lipophilic corneal epithelium is the major barrier to penetration of topically applied drugs. The underlying corneal stroma is hydrophilic, while the posteriorly located corneal endothelium is lipophilic. This lipophilic–hydrophilic–lipophilic layering limits intraocular movement of all but biphasic drugs, which have combined hydrophilic and lipophilic structural properties. Thus, treatment of disease conditions beyond the corneal barrier necessitates knowledge of drugs that effectively penetrate this barrier, either by their biphasic structure, or by susceptibility to alterations within the ocular environment itself. An example of medications altered by the ocular environment to improve penetration are the prostaglandin analogues, which are converted by esterases within the cornea, thus improving migration through the corneal layers.

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

The blood–aqueous barrier and blood–retinal barriers are the major impediments to penetration of systemically administered drugs. Lipid-soluble, low-molecular-weight drugs are most able to penetrate intact (non-inflamed) barriers, while compromise of these barriers with inflammation increases the intraocular movement of larger, less lipid-soluble drugs, while generally maintaining the ability of lipid-soluble, low-molecular-weight drugs to penetrate.

The hyaloideocapsular ligament, located at the junction of the posterior lens capsule and anterior vitreous, is a barrier to the movement of drugs between the anterior and posterior segments of the eye. Disruption of this barrier, as may occur with intraocular surgery or lens luxation, increases posterior movement of topically applied drugs, and anterior movement of systemically administered drugs.

Drug Factors

Solubility impacts drug disposition within the eye, with biphasic and lipophilic drugs most readily able to penetrate the eye following administration topically and systemically, respectively. Additionally, low-molecular-weight drugs are more able to penetrate ocular barriers.

Administration of drugs formulated at physiological pH (~pH 7 to pH 7.4) best avoids discomfort upon instillation, thus improving drug availability, as irritation leads to tearing and subsequent drug washout. Drugs that require formulation at nonphysiological pH to maintain stability may be combined with buffers at the time of administration to improve comfort upon administration and subsequent retention on the ocular surface.

The formulation of topical medications also impacts drug disposition, and generally fall into the categories of solution, suspension, or ointment. Chapter 5 reviews the pharmaceutical science behind formulations. Solutions are generally easier to administer to small animals, and may be administered to large animals through subpalpebral lavage systems; however, spillage over the lids may occur with dosing quantities that are too large. The volume of drops from commercially manufactured dropper bottles ranges from 25 to 70 μl. As the palpebral fissure of dogs and cats holds only approximately 30 μl, administration of more than one drop at a time is likely to lead to overflow and spillage and subsequent loss of drug.

Suspensions are composed of larger particles suspended in an aqueous vehicle, and are administered from a dropper bottle. While generally minimally irritating, the particle size must be carefully controlled to avoid stimulating greater tear production and subsequent washout.

Ointments contain drugs within various viscous vehicles, such as petrolatum and lanolin. Advantages of ointments include the ability to administer lipid-soluble drugs, and to achieve a longer contact time with less drainage through the nasolacrimal system. A disadvantage of ointments, however, is the oily residue frequently remaining following administration.

Administration Factors

Medications to treat ocular disease are most commonly administered either topically or orally/parenterally, with local ocular injections (i.e., subconjunctival, intracameral, intravitreal) indicated in very specific circumstances.

Depending on specific drug factors (see Section Drug Factors), topical administration enables high levels of medication to be reached locally, specifically within the conjunctiva, cornea, and potentially the anterior chamber. Additionally, topical administration minimizes systemic exposure, thus minimizing the potential for adverse drug reactions or interactions. Systemic (oral, parenteral) medication is indicated for the treatment of eyelid and orbital disease, due to the restricted penetration of topical medications to these tissues, as well as extensive vascularization of the regions. Additionally, posterior segment disease is usually most effectively managed with systemic medications due to the presence of the corneal and hyaloideocapsular barriers anteriorly.

Subconjunctival administration involves the injection of medication into the space between the conjunctiva and the sclera. Such medications will then either penetrate the eye through the sclera and cornea or be absorbed by the conjunctival vasculature, thus increasing systemic exposure. Less commonly used, intracameral administration involves the injection of medication into the anterior chamber, allowing movement of drug within the intraocular environment and subsequent drainage from the eye with the AH. In addition to a brief residence time within the eye, intracameral injection carries a greater risk of both iatrogenic damage associated with the injection itself, and direct intraocular toxicity induced by drug on delicate intraocular structures. Intravitreal administration involves the injection of medication into the vitreous, which serves as a long-term reservoir of drug within the eye. These high and potentially sustained local drug levels increase the likelihood of both intraocular and systemic dissemination relative to that associated with topical administration. Peribulbar or retrobulbar injection involves injection of medication behind the globe, and is reserved for placement of local anesthetics around the globe to provide both akinesia and analgesia in association with ocular procedures. Regarding all four routes of ocular/periocular injection, each should be used sparingly (if at all) and only with detailed knowledge of potential side effects and toxicities (both ocular and systemic) of the specific drug being injected.

Table 49.1 Topically administered ocular hypotensives available for use in veterinary ophthalmology

Drug class	Representative agents	Suggested frequency	Contraindications
Beta-blockers	Timolol (0.25%, 0.5%) Betaxolol (0.25%, 0.5%)	q 12 h	Asthma Heart disease
Carbonic anhydrase inhibitors	Dorzolamide (2%) Brinzolamide (1%)	q 8–12 h	
Prostaglandin analogues	Latanoprost (0.005%) Bimatoprost (0.03%) Travoprost (0.004%)	q 12–24 h	Pupillary block glaucoma (uveitis, anterior lens luxation)
Parasympathomimetics	Pilocarpine (1–2%) Demecarium bromide (0.125–0.25%)	q 12–24 h	Pupillary block glaucoma (uveitis, anterior lens luxation)

In addition to the route of administration, frequency of administration may impact the success of therapy of ocular diseases. An advantage of topical administration is the ability to vary the frequency in association with the indication and the severity of the disease process. For example, prophylactic antimicrobial therapy of an uninfected corneal ulcer is appropriate and generally preferred to occur at a frequency of every 6 to 8 hours, while therapeutic administration of an infected corneal ulcer may be as frequent as every hour, thus potentially increasing the effectiveness of medical therapy.

Glaucoma

Physiology of Glaucoma

The intraocular pressure (IOP) is maintained by a balance between production and drainage of AH. Production of AH by the ciliary body occurs primarily via active secretion, utilizing both the carbonic anhydrase enzyme system and cAMP-mediated mechanisms. Following production posterior to the pupil, AH flows anteriorly through the pupil and drains out of the eye via conventional and unconventional outflow at the ICA. Conventional outflow through the trabecular meshwork into scleral vessels drains the majority of AH, while unconventional (uveoscleral) outflow drains the remainder (15% in dogs, 3% in cats, as much as 60–70% in horses).

Glaucoma is characterized by increased IOP, resulting in retinal and optic nerve damage and subsequent vision loss, as well as variable degrees of discomfort. Glaucoma is always caused by decreased drainage, either due to an inherent abnormality in the drainage angle itself (primary glaucoma) or obstruction of AH flow within or from the eye (secondary glaucoma).

Pharmacological Therapy of Glaucoma

Medical management of glaucoma is achieved utilizing medications that either decrease AH production or increase AH drainage (Table 49.1). It is important to note that, while drug studies frequently utilize normotensive eyes to determine IOP-lowering effects of individual drugs in various species, reductions achieved in glaucomatous eyes are frequently relatively greater.

Beta-blockers

Representative agents: 0.25%, 0.5% timolol (nonselective); 0.25%, 0.5% betaxolol (β_1-selective).

Mechanism of action: Beta-blockers decrease AH production by an unknown mechanism; however, interaction with either cAMP or Na^+/K^+-ATPase (or both) enzyme systems is speculated to be involved.

Dosing/efficacy: Beta-blockers are generally indicated for twice-daily topical ophthalmic dosing as maintenance (rather than emergency) therapy. Reduction of IOP by 4–5 mmHg is achieved in dogs with glaucoma, reduction of 4 mmHg is achieved in normotensive cats, and reduction of 7 mmHg is achieved in normotensive horses.

Side effects/contraindications: Beta-blockers are known to be absorbed systemically, and may induce bradycardia and systemic hypotension. They also may exacerbate asthma and compensated heart disease due to nonspecific beta-receptor blockade. It is therefore generally recommended to avoid use in small dogs and cats (i.e., <10 kg), particularly those with a history of cardiovascular disease.

Carbonic Anhydrase Inhibitors

Representative agents: 2% dorzolamide (topical); 1% brinzolamide (topical); methazolamide (oral); acetazolamide (oral).

Mechanism of action: Carbonic anhydrase inhibitors (CAIs) decrease AH production by blockade of the carbonic anhydrase enzyme system in the ciliary body epithelium. Conversion of CO_2 to HCO_3^- and subsequent movement of H_2O into the posterior chamber is thus inhibited, resulting in decreased IOP.

Dosing/efficacy: CAIs are generally indicated for three-times daily dosing as maintenance therapy, but may be used as frequently as every 15 to 30 minutes in the emergency management of acute glaucoma. Dorzolamide and brinzolamide have comparable efficacy in glaucomatous dogs, lowering IOP by 7–15 mmHg. Brinzolamide did not lower IOP in normotensive cats. Dorzolamide and brinzolamide lowered IOP by 2 and 5 mmHg, respectively, in normotensive horses.

Side effects/contraindications: Topical formulations may cause local ocular discomfort upon administration. Systemic administration may lead to metabolic acidosis due to diuretic effects. Systemic side effects generally do not develop with topical administration. Combined use of topical and systemic formulations has not been shown to be additive.

Prostaglandin Analogues

Representative agents: 0.005% latanoprost; 0.03% bimatoprost; 0.004% travoprost.

Mechanism of action: Prostaglandin (PG) analogues, which are chemically modified versions of the endogenous PG PGF_2, decrease IOP by increasing uveoscleral (nonconventional) AH outflow through activation of FP receptors. A marked rapid reduction in IOP is noted; however, the precise mechanism for the acute reduction in IOP is unknown. The long-term IOP reduction achieved with PG analogues is linked to structural alterations within the trabecular meshwork portion of the ICA. Current PG analogues are prodrugs, with the administered form of the drug converted by corneal esterases into the active form, thus increasing the local, rather than systemic, drug effects.

Dosing/efficacy: PG analogues are indicated for once- to twice-daily dosing as maintenance therapy in dogs with primary glaucoma, with twice-daily dosing producing more consistent IOP-lowering effects. Dosing may be as frequent as every 15 to 30 minutes when managing acute glaucoma in an emergency situation. Clinically significant IOP reductions of 20–60% result from latanoprost, travoprost, and bimatoprost administration to glaucomatous canine eyes. Current PG analogues are ineffective in cats due to receptor selectivity (ocular hypotensive effects in cats are mediated by EP receptors, which PG analogues do not possess affinity for). A clinically insignificant reduction in IOP of 1–3 mmHg is achieved following administration to normotensive horses.

Side effects/contraindications: Conjunctival hyperemia and moderate to marked miosis are noted in canine eyes. Due to the miotic effects, PG analogues are contraindicated in most cases of secondary glaucoma (i.e., glaucoma resulting from blockage of the pupil and subsequent obstruction of AH flow, which is exacerbated by miosis). Some discomfort may occur with instillation. Glaucomatous cats and horses are ineffectively managed with PG analogues, due to receptor specificity in cats and due to the significant inflammatory side effects (conjunctival hyperemia, miosis, flare) in horses.

Hyperosmotic agents

Representative agents: mannitol 20% (intravenous); glycerol (oral).

Mechanism of action: Administration of hyperosmotic agents causes the serum to become hyperosmotic to intraocular fluids, resulting in both fluid movement from the AH and VH, as well as a reduction in ultrafiltration of plasma (which contributes a small volume to AH production). Dehydration of the VH may also mechanically open the ICA by pulling the anterior vitreous face, lens, and iris leaflets posteriorly.

Dosing/efficacy: Mannitol is administered IV at a dose of 1 g/kg over 15–20 minutes, with coinciding water depravation for 4–6 hours postadministration, in the management of acute primary glaucoma only. Maximum IOP reduction of approximately 10 mmHg (normotensive dogs) is generally achieved within 2 hours. Glycerol is administered at a dose of 1–2 g/kg orally, and, in contrast to mannitol, may be administered as a component of long-term management.

Side effects/contraindications: The most significant ocular contraindication to the use of hyperosmotic agents is the presence of anterior uveitis, which is associated with leakage of blood constituents through the normally minimally permeable blood–aqueous barrier. Such leakage enables the hyperosmotic agent to leak in to the eye, resulting in an intraocular fluid shift and corresponding increase in IOP. Systemic contraindications to the use of hyperosmotic agents include cardiovascular disease (expansion of extracellular fluid volume will lead to exacerbation of cardiac failure), renal disease, and diabetes mellitus (glycerol is converted to glucose). Glycerol may also induce vomiting, particularly at higher doses. Due to systemic side effects and contraindications and the advent of more effective topical medications,

Table 49.2 Examples of topically administered corticosteroid formulations available for use in veterinary ophthalmology

Agent	Formulation	Indications	Contraindications
Prednisolone acetate (1%)	Suspension	Ocular surface inflammation Anterior intraocular inflammation	Corneal ulceration Nonulcerative corneal infection (stromal abscess)
Dexamethasone sodium phosphate (0.1%)	Solution Ointment	Ocular surface inflammation Anterior intraocular inflammation	Corneal ulceration Nonulcerative corneal infection (stromal abscess)
Hydrocortisone 0.5–1%	Solution Ointment	Ocular surface inflammation	Corneal ulceration Nonulcerative corneal infection (stromal abscess) Intraocular inflammation

use of hyperosmotic agents in veterinary ophthalmology is limited.

Parasympathomimetics

Representative agents: 1–2% pilocarpine (direct acting); 0.125%–0.25% demecarium bromide (indirect acting).

Mechanism of action: Parasympathomimemtics increase outflow by inducing miosis, thus widening the ICA and increasing AH outflow.

Dosing/efficacy: Pilocarpine is generally indicated for administration three to four times daily, and leads to 30–40% IOP reduction in glaucomatous dogs.

Side effects/contraindications: The acidic pH of pilocarpine solution causes irritation following topical administration. Due to the induction of miosis, pilocarpine is contraindicated in patients with uveitis and/or pupillary block glaucoma. The effect of parasympathomimetics on IOP is minimal compared to other classes of ocular hypotensive agents.

Ocular Inflammation and Antiinflammatory Therapy

Ocular inflammation is meant to serve a protective function; however, significant structural damage is induced by the inflammatory reaction, which in turn may have deleterious effects on vision and comfort. Antiinflammatory therapy is therefore essential to minimize secondary effects of inflammation, and to preserve ocular structure and function. Indications for therapy with topical antiinflammatories include the management of ocular surface inflammation (conjunctivitis, keratitis) and anterior segment inflammation (anterior uveitis). Systemic antiinflammatories are indicated for management of posterior uveitis.

Pharmacological Management of Intraocular Inflammation

Corticosteroids

Representative agents (Table 49.2)**:** 0.1% dexamethasone sodium phosphate; 1% prednisolone acetate; 1% hydrocortisone.

Mechanism of action: Corticosteroids bind to cellular glucocorticoid (GC) receptors, translocate to the nucleus, bind hormone responsive elements (HREs), and exert antiinflammatory effects through inhibition of the arachidonic acid cascade. These effects may be positive modulation via inducing expression of antiinflammatory proteins (i.e., lipocortin), or negative modulation via inhibiting expression of proinflammatory molecules (i.e., prostaglandins, cytokines). These mechanisms are more fully described in Chapter 29.

Dosing/efficacy: The location and severity of ocular inflammation determine both the frequency of administration and drug selection. Ocular surface inflammation may be effectively treated with topical hydrocortisone; however, hydrocortisone is ineffective for deep corneal or anterior uveal inflammation, due to its inability to penetrate the cornea. *Therefore, to effectively treat deep keratitis or anterior uveitis, a formulation, such as prednisolone acetate or dexamethasone alcohol, that effectively penetrates the cornea to reach the anterior segment is necessary.* Regardless of the location of inflammation, severely inflamed eyes may require every 2–4 hour dosing, while every 8–12 hour dosing may be indicated with lesser degrees of inflammation.

Side effects/contraindications: Long-term topical administration may result in the formation of corneal deposits

Table 49.3 Examples of topically administered nonsteroidal antiinflammatory formulations available for use in veterinary ophthalmology

Agent	Formulation	Indications	Contraindications
Flurbiprofen 0.03%	Solution	Ocular surface inflammation	Individual sensitivity
Diclofenac 0.1%	Solution	Anterior segment inflammation	Monitor with corneal ulceration
Ketorolac 0.5%	Solution		
Bromfenac 0.9%	Solution		
Nepafenac 0.1%	Solution		

(degeneration). Systemic absorption may occur with frequent and/or long-term administration, adversely affecting coinciding endocrine imbalances (such as diabetes mellitus, hyperadrenocorticism). *Topical corticosteroids are contraindicated in the presence of a corneal ulcer,* due to inhibited reepithelialization of the corneal wound and potentiation of ocular surface infections.

Nonsteroidal Antiinflammatory Agents

Representative agents (Table 49.3)**:** 0.03% flurbiprofen; 0.1% diclofenac; 0.5% ketorolac; 0.9% bromfenac; 0.1% nepafenac.

Mechanism of action: Nonsteroidal antiinflammatory agents (NSAIDs) exert antiinflammatory effects by inhibiting the production of PG through the constitutive cyclooxygenase-1 (COX-1) and the inducible cyclooxygenase-2 (COX-2) enzyme systems. These mechanisms are fully described in Chapter 20 of this text.

Dosing/efficacy: As with corticosteroids, frequency of administration of topical NSAIDs depends upon the severity of the inflammation, with administration being as frequent as every 2–4 hours, or as infrequent as every 12–24 hours. NSAIDs are considered less effective than topical corticosteroids in the management of ocular inflammatory diseases. Transcorneal penetration of NSAIDs is variable; however, newer agents (bromfenac, nepafenac) are reported to have improved penetration (and therefore potentially improve therapeutic effect) relative to older NSAIDs, such as flurbiprofen.

Side effects/contraindications: While safer to use in the presence of corneal ulceration than topical corticosteroids, topical NSAIDs may inhibit reepithelialization of the cornea, and have been associated with acute corneal melts. Systemic uptake is less of a concern than with topical corticosteroids.

Ocular Infections and Antimicrobial Therapy

Antibacterial agents

As with antibacterial therapy for other body systems, ocular use may be either prophylactic or therapeutic. It is important to consider that, while certain gram-negative bacteria (such as *Pseudomonas aeruginosa*) are known to be potent ocular pathogens, the majority of ocular infections are caused by pathogenic effects of normal ocular surface bacteria, which are predominantly gram-positive. Therefore, when considering the appropriate antibiotic choice for prophylactic therapy, an agent with gram-positive activity is important.

The general principles of ocular antimicrobial therapy are:

1) Prophylactic use is always indicated for superficial, uncomplicated corneal ulcers.
2) Prophylactic use is indicated in association with adnexal surgical procedures in which the ocular surface (generally conjunctiva) is involved.
3) Therapeutic use is indicated for infected, complicated corneal diseases, such as ulcers and abscesses.
4) Therapeutic use is indicated for bacterial endophthalmitis.
5) When possible, cytology and culture/sensitivity results should guide antibiotic selection.
6) Ability of a specific antibiotic formulation to reach desired site of infection (deep cornea, anterior chamber) should guide antibiotic selection.
7) Side effects, both ocular and systemic, must be considered.

"Double Antibiotic" and "Triple Antibiotic" Preparations

Representative agents: neomycin, polymyxin B, gramicidin (solution); neomycin, polymyxin B, bacitracin (ointment); other combinations may be commercially available as well.

Spectrum: Gram-negative (neomycin, polymyxin B), and gram-positive (bacitracin, gramicidin) bacteria.

Indications/dosing: Due to broad-spectrum activity, combination products are useful for prophylaxis for ocular surface infections. Cases that have infection but have not been receiving a combination product may also be effectively managed. The lack of intraocular penetration limits usefulness in the presence of deep corneal infections or bacterial endophthalmitis. Dosing can be as frequent as hourly if therapeutic, or three times daily if prophylactic.

Side effects/contraindications: Hypersensitivity to neomycin may result in blepharoconjunctivitis. A potential (but rare) anaphylactic reaction to neomycin may occur in cats, thus use of combination products in cats is generally not advised.

Additional information: A common antibiotic–corticosteroid combination product, neomycin/polymyxin B/dexamethasone, is useful for treatment of ocular surface inflammation and secondary bacterial infection. It is critical to ensure, however, that such products are avoided when a corneal ulcer is present, due to the corticosteroid component. Proper education of staff and storage of products with and without corticosteroids in separate areas is encouraged.

Aminoglycosides

Representative agents: 0.3% tobramycin; 0.3% gentamicin (also, neomycin as component of above preparations).

Spectrum: Predominantly gram-negative, with gram-positive restricted to *Staphylococcus aureus.* There is good efficacy versus *Pseudomonas aeruginosa*, although increasing resistance has been reported. Due to inherent resistance, aminoglycosides are inactive versus anaerobes. See Chapter 35 for further discussion.

Indications/dosing: Used as prophylaxis or therapy for ocular surface infections, aminoglycosides have variable intraocular penetration, which limits use in patients with deep corneal infections or bacterial endophthalmitis. Dosing can be as frequent as hourly if therapeutic, or three times daily if prophylactic.

Side effects/contraindications: Of the aminoglycosides (and topical antibiotics in general), gentamicin demonstrates comparatively high toxicity to the epithelium. It must be considered, therefore, that its use in the presence of corneal ulcerations may be associated with decreased wound healing. In cases with documented infection and appropriate susceptibility, use of gentamicin is warranted.

Tetracyclines

Representative agent: 0.5% oxytetracycline (formulated with polymyxin B).

Spectrum: Good activity versus intracellular organisms, with poor efficacy versus *Pseudomonas aeruginosa, Staphylococcus* spp., and *Streptococcus* spp. See Chapter 34 for further discussion.

Indications/dosing: Oxytetracycline is useful for prophylaxis or therapy for ocular surface infections, particularly in cats. As a tetracycline, antimatrix metalloproteinase activity may improve keratomalacia. In addition, tetracyclines have demonstrated increased corneal epithelial wound healing, which is presumed to be in association with modulation of transforming growth factor beta (TGF-β) activity. Dosing for prophylaxis is generally three times daily, and for therapy can be as frequent as hourly.

Side effects/contraindications: Local ocular irritation may occur.

Fluoroquinolones

Representative agents: 0.3% ofloxacin; 0.3% ciprofloxacin (solution, ointment); 0.5% levofloxacin; 0.5% moxifloxacin; 0.3% gatifloxacin; 0.6% besifloxacin.

Spectrum: Older agents (ofloxacin, ciprofloxacin, levofloxacin) are more effective versus gram-negative bacteria, while newer agents (moxifloxacin, gatifloxacin) have increased gram-positive efficacy. See Chapter 37 for further discussion.

Indications/dosing: Older agents may be appropriately used for prophylaxis or therapy of ocular surface and intraocular infections. Ofloxacin demonstrates greater corneal penetration than ciprofloxacin, therefore may be more appropriately used in cases with deep corneal or intraocular infections. Newer agents are indicated for therapeutic use only, in patients with known ocular surface or intraocular infection. Dosing can be as frequent as hourly if therapeutic, or three times daily if prophylactic.

Side effects/contraindications: Fluoroquinolones may induce drug precipitation within cornea. Local irritation is rare.

Other Topical Ophthalmic Antibacterials

Chloramphenicol (1% ointment)

Spectrum: Gram-positive and gram-negative bacteria, and intracellular organisms.

Indications/dosing: Prophylaxis or therapy of ocular surface infections is provided by administration two or more times daily.

Side effects/contraindications: Fluoroquinolones *may* be associated with dose-responsive bone marrow suppression (reversible upon discontinuation of medication). Fluoroquinolones *may* be associated with idiosyncratic aplastic anemia (which is irreversible, and generally occurs after drug administration has already been discontinued).

Erythromycin (0.5% ointment)

Spectrum: Gram-positive bacteria, *Chlamydophila felis*, *Mycoplasma* spp.

Indications/dosing: Prophylaxis or therapy of ocular surface infections is provided by administration two or more times daily.

Side effects/contraindications: Local ocular irritation may occur; however, this is generally mild.

Antifungal agents

The most frequent indication for antifungal agents in veterinary ophthalmology is in the treatment of fungal infections of the cornea (keratomycosis) in horses. Such infections are common in warm, humid climates, and are most commonly caused by filamentous organisms such as *Aspergillus* spp. and *Fusarium* spp. See Chapter 38 for further discussion of antifungal drugs.

Polyenes

Representative agents: 5% natamycin; amphotericin B.

Mechanism of action: Polyenes bind ergosterol in the fungal cell membrane, forming a polyene–sterol complex. This complex induces membrane permeability, allowing leakage of intracellular nutrients and resulting in cell lysis. Depending on the concentration achieved at the site of infection and organism susceptibility, action may be either fungistatic or fungicidal.

Dosing: Both agents are considered broad spectrum; however, activity versus *Aspergillus* spp. may be weaker than versus other filamentous organisms. Polyenes have poor penetration following topical administration to a cornea with an intact epithelium, thus natamycin is generally administered in cases of confirmed ulcerative keratomycosis, as frequently as hourly in initial stages of treatment. Amphotericin B has anecdotally been administered subconjunctivally to minimize irritation associated with frequent topical administration; however, this should be performed under the guidance of a veterinary ophthalmologist.

Side effects/contraindications: Local ocular irritation is the primary side effect. Systemic administration of amphotericin B may induce nephrotoxicity. Concern of systemic uptake associated with subconjunctival administration is minimal due to the small dose relative to body weight.

Azoles

Representative agents: 1% voriconazole (formulation for IV injection); 1% miconazole (compounded); 1% itraconazole/30% dimethyl sulfoxide (DMSO) (compounded); ketoconazole (oral); fluconazole (oral).

Mechanism of action: Azoles inhibit the synthesis of ergosterol in the fungal cell membrane, increasing membrane permeability and leading to cell lysis. Additionally, inhibition of intracellular enzyme activity leads to accumulation of toxic intracellular metabolites.

Indications/dosing: Azoles are broad spectrum versus filamentous fungi, and are generally better versus *Aspergillus* spp. than *Fusarium* spp. Administration of topical agents is indicated in cases of ulcerative and nonulcerative keratomycosis, as frequently as hourly in initial stages of therapy. Although less important in ocular surface therapy than topical administration, oral antifungal agents may be indicated in cases of keratomycosis. In horses with keratomycosis, fluconazole may be administered orally (14 mg/kg once, then 5 mg/kg orally every 24 hours).

Side effects/contraindications: Topical ocular irritation is generally minimal. Monitoring liver enzymes may be indicated in animals receiving oral azoles. Oral fluconazole has been implicated in prolonged recovery from anesthesia in horses, possibly due to interactions with midazolam and ketamine.

Antiviral Agents

The most common indication for antiviral agents in veterinary ophthalmology is the treatment of feline herpesvirus-1 infections, which manifest as ocular surface disease in cats. Dogs and horses also may experience herpetic ocular surface disease; however, investigations into efficacy of available antiviral agents towards canine and equine herpesvirus variants are fewer than those involving feline herpesvirus-1. See Chapter 38 for further discussion of antiviral drugs.

Pyrimidine Analogues

Representative agents: 1% trifluridine; 0.1–2.5% idoxuridine (compounded).

Mechanism of action: Pyrimidine analogues are selectively incorporated into viral DNA in the place of thymidine, disrupting viral DNA synthesis.

Indications/dosing: As pyrimidine analogues exert their action on DNA synthesis, they are only active when virus is actively replicating. In association with the cytopathic viral effect, active viral replication is indicated by the presence of corneal and/or conjunctival ulceration. As they are virustatic rather than virucidal, frequent administration (five to eight times/day) in the presence of ocular surface ulceration is necessary.

Side effects/contraindications: The most commonly reported side effect is topical ocular surface irritation.

Purine Analogues

Representative agents: 1–3% vidarabine; 0.5% cidofovir; famciclovir (oral); (*acyclovir – see Side effects/contraindications*; *valacyclovir – see Side effects/contraindications*).

Mechanism of action: Purine analogues undergo an initial phosphorylation step by viral thymidine kinases, with subsequent intracellular transformations resulting in inhibition of viral DNA synthesis.

Indications/dosing: While still virustatic rather than virucidal, cidofovir has the advantage of necessitating only twice daily topical dosing, while vidarabine is generally dosed topically similarly to the pyrimidine analogues (five to eight times/day). The appropriate oral dose has not been determined for famciclovir at this time; however, doses of 62.5 mg once to twice daily have been anecdotally reported as efficacious in the treatment of FHV-1-mediated disease, while doses as high as 90 mg/kg three times daily have been evaluated as safe in experimental situations.

Side effects/contraindications: Topical ocular irritation may occur with topical administration. Nasolacrimal punctal occlusion has been reported in conjunction with cidofovir administration in people. *Acyclovir and valacyclovir should not be administered to cats (orally or topically) due to life-threatening toxicities (kidney, bone marrow).*

Lacrimogenics

Lacrimogenics are drugs that increase tear production in cases of immune-mediated and neurogenic keratoconjunctivitis sicca (KCS).

T-cell inhibitors

Representative agents: 0.2–2% cyclosporine (commercially available, compounded); 0.03% tacrolimus (compounded).

Mechanism of action: Calcineurin inhibitors bind cyclophilin (cyclosporine) or FK-binding proteins (tacrolimus), subsequently inhibiting T-lymphocyte proliferation.

Indications/dosing: Topical administration is only appropriate for ocular surface disease (i.e., KCS, pigmentary keratitis, superficial keratitis), due to insufficient intraocular penetration for treatment of intraocular diseases (i.e., anterior uveitis). Treatment is generally twice daily, allowing a minimum of 4 weeks of therapy to determine response. Systemic administration may be utilized in the treatment of immune-mediated inflammatory diseases such as uveodermatological syndrome. Sustained-release, surgically implanted subconjunctival cyclosporin implants have been developed as treatment for Immune-Mediated Keratitis in horses and have been used with success as treatment for KCS in dogs that are not amenable to daily topical treatment. Sustained-release, surgically implanted suprachoroidal cyclosporine implants have been developed for treatment of Equine Recurrent Uveitis as well, but these are not indicated for treatment of ocular surface disease. Placement of these implants is best performed by a veterinary ophthalmologist with microsurgical training.

Side effects/contraindications: Topical administration of cyclosporine has resulted in suppression of cellular immunity in dogs; however, the clinical significance appears to be minimal. The effect of topical cyclosporine on viral (herpetic) keratitis is unknown.

Parasympathomimetic

Representative agent: 2% pilocarpine.

Mechanism of action: As a direct-acting parasympathomimetic, pilocarpine mimics acetylcholine at the terminal synapse. Dogs with neurogenic KCS are lacking neurological input to an otherwise normal lacrimal gland, thus pilocarpine bypasses the interrupted neurological pathways and provides direct stimulation to the lacrimal gland. See Chapter 8 for further discussion of the mechanism of action of this drug.

Indications/dosing: Oral administration of the 2% ophthalmic solution is utilized, generally starting as 1 to 2 drops per 20 pounds twice daily, applied on the food, and increasing until tear production is achieved.

Side effects/contraindications: Adverse systemic effects may be noted as dosing increases, resulting in signs of parasympathetic overstimulation and excessive salivation, lacrimation, urination, and defecation. When these signs are present, administration must be decreased.

Mydriatics and Cycloplegics

Mydriatics (drugs that dilate the pupil) are indicated primarily for diagnostic examination, while those with coinciding cycloplegic action that paralyze ciliary body muscle spasm are indicated for therapy of anterior uveitis.

Sympathomimetics

Representative agents: 0.1%, 1%, 2% epinephrine; dipivalyl epinephrine; 2.5%, 10% phenylephrine.

Mechanism of action: Sympathomimetics directly stimulate α-adrenergic receptors of the iris dilator muscle, producing mydriasis without cycloplegia. See Chapter 7 for further discussion.

Indication: Sympathomimetics are used to augment mydriasis achieved by parasympatholytics prior to intraocular surgery, and to diagnose Horner's syndrome.

Dosing/efficacy: Use of sympathomimetics when indicated is generally restricted to one to two drops topically, without repeated dosing. Their efficacy as mydriatic agents is less than that of parasympatholytic agents, thus they are generally not used alone for either diagnostic or therapeutic purposes.

Side effects: Ocular surface irritation may occur following topical administration. Systemic absorption may induce systemic hypertension, thus use of these agents should be limited in patients with preexisting cardiovascular disease, or in small (i.e., <10 kg) patients.

Parasympatholytics

Representative agents: 0.5%, 1% tropicamide; 1% atropine.

Mechanism of action: Parasympatholytics induce anticholinergic blockade of iris sphincter and ciliary body muscles, thus inducing mydriasis while producing cycloplegia. Additionally, stabilization of a leaking blood–aqueous barrier is achieved with atropine, thus partially mitigating the increased permeability associated with inflammation. Inflammation decreases the efficacy of parasympatholytics; however, due to stimulation of acetylcholine receptors on the iris sphincter muscles, higher drug concentrations are required to achieve pharmacological blockade. Mydriasis achieved with parasympatholytics is greater than that achieved with sympathomimetics, as the iris sphincter muscle is more powerful than the iris dilator muscle.

Dosing/efficacy: Dosing of parasympatholytics for diagnostic evaluation (tropicamide) is one to two drops topically once at the time of examination, with mydriatic effects generally wearing off within 6–8 hours. Dosing of parasympatholytics in the treatment of anterior uveitis (atropine) is to effect, as gauged by the induction of mydriasis. Depending on the degree of intraocular inflammation, one drop generally every 12–48 hours is appropriate. In addition to being influenced by disease process, relative efficacy is also dependent upon species; for example, mydriasis due to atropine lasts 4–5 days in normal canine eyes, versus up to 14 days in normal equine eyes. Relative efficacy also depends upon iridal pigmentation, as pigment serves as a reservoir for drug, slowing onset of action and prolonging duration in heavily pigmented versus poorly pigmented eyes.

Side effects/contraindications: Salivation may be induced following topical administration due to drainage of bitter-tasting atropine solution into the oral cavity via the nasopharynx. Temporary reduction in aqueous tear film production occurs. Photophobia may occur due to mydriasis.

Local Anesthetics

Topical local anesthetics are frequently administered to provide corneal and conjunctival anesthesia when performing routine diagnostic and therapeutic procedures, such as tonometry, cytology collection, and corneal or intraocular surgery.

Representative agents: 0.5% proparacaine; 0.5%, 1% tetracaine.

Mechanism of action: Local anesthetics interfere with nerve cell sodium channels, blocking the intracellular movement of sodium into nerve cells and thus inhibiting depolarization. See Chapter 15 for further discussion on local anesthetic mechanism of action.

Dosing/efficacy: Following administration of a single drop in dogs, anesthetic effect of proparacaine is noted within 1 minute, reaching maximal effect within 15 minutes, for a total duration of effect of 45 minutes. A second drop administered 5 minutes after the first can extend the duration of action to 55 minutes. In both cats and horses, a single drop of proparacaine results in anesthetic effect within 1 minute and lasts 25 minutes. Tetracaine administration in horses has a dose-dependent effect, with the 1% concentration exhibiting longer duration of anesthetic effect than the 0.5% solution (50 versus 30 minutes, respectively).

Side effects/contraindications: Proparacaine causes transient tear film instability, and repeated dosing may result in punctate epithelial keratitis, necrotizing keratitis, or severe infiltrative keratitis. Therefore, topical local anesthetics are *absolutely contraindicated* as therapy for any ocular surface disease, and repeated dosing should be performed with caution in a diagnostic setting. Topical local anesthetics may exert antimicrobial effects, thus samples for culture are ideally collected prior to administration. This may not be feasible in a clinical setting, however, due to the need to minimize patient discomfort in order to maximize patient cooperation.

Pharmacogenomics

Katrina L. Mealey

A patient's response to a drug includes both beneficial (therapeutic) effects as well as any adverse effects, including lack of therapeutic efficacy. While the goal of drug therapy is to produce a specific pharmacological effect without producing adverse effects, it is often difficult to predict how effective or how safe a medication may be for a particular patient. If 10 patients with the same disease were administered the same drug, each might respond differently with respect to both drug efficacy and the likelihood of an adverse reaction. A number of factors may influence a patient's response to drug therapy, including the patient's age, species, concurrent medications, diet, health or disease status, and others. Many of these are discussed in Chapter 2 of this text. However, consideration of all of these factors is often not sufficient to explain the degree of interpatient variation observed. The observed interpatient variability in drug response may result from genetically determined differences in drug metabolism, drug distribution, and/or receptors or drug target proteins. The branch of pharmacology that involves identifying genetic variations leading to interindividual differences in drug response is called *pharmacogenetics*. Pharmacogenetics is likely the ultimate way to establish the right drug and dose for each patient, thereby optimizing efficacy and minimizing toxicity. Despite the fact that this branch of pharmacology is still in its infancy as a science, a number of important discoveries have already contributed to improved pharmacotherapy in human and veterinary patients.

The term *pharmacogenetics* is often used interchangeably with the term *pharmacogenomics*. Strictly speaking, pharmacogenetics refers to monogenetic (single gene) variants that affect a patient's response to a particular drug. An example of a pharmacogenetic study might be one that examines the influence of mutations in the thiopurine methyl transferase gene on the response to azathioprine. Pharmacogenomics, on the other hand, refers to the entire spectrum of genes that are involved in determining a patient's response to a particular drug. An example of a pharmacogenomic study would be one that examines the interaction between cytochrome P450 genes, β_1, β_2, α_1, and α_2-adrenergic receptor genes, and drug transporter (i.e., *MDR1*) genes on the response to carvedilol. The relatively few reports of gene–drug responses in veterinary medicine are pharmacogenetic in nature. While dramatic alterations in drug response have been identified in pharmacogenetic studies, a patient's overall response to a particular drug will likely require a pharmacogenomics approach to characterize (and summate) the individual contribution of multiple genes to drug response. For the purposes of this chapter, the terms *pharmacogenetics* and *pharmacogenomics* will be used interchangeably.

The concept that inheritance might explain individual variation in susceptibility to adverse drug reactions and/or variation in drug efficacy was proposed in 1957. The term *pharmacogenetics* was coined shortly afterward, in 1959. Relatively little pharmacogenetic research occurred for the next three decades. A resurgence in pharmacogenetic research occurred coincidentally with the initiation of the Human Genome Project in 1990. Since then, research in pharmacogenetics has expanded at a remarkable rate. There are now at least five journals exclusively devoted to pharmacogenetic/pharmacogenomic research, and many other medical and pharmacological journals encouraging submissions reporting results of pharmacogenetic research. Following completion of the Human Genome Project (announced in 2003), the National Human Genome Research Institute challenged investigators to develop genome-based approaches to predict drug response, setting the stage for continued growth in the field of pharmacogenetics.

Basic Genetic Concepts

The human genome contains approximately 3 billion nucleotide bases, representing roughly 30,000 genes. When a gene is expressed, DNA is transcribed into RNA, which is then translated to make proteins. Three consecutive nucleotide bases form a specific codon,

specifying the addition of a particular amino acid or signaling amino acid chain termination (stop codons). The genetic code is said to have redundancy, which simply means that there may be two or more different codons for the same amino acid. In humans, for example, both GGA and GGC code for the amino acid glycine. Redundancy exists in the canine genome as well, with TAA, TGA, and TAG all representing stop codons. A gene is simply the DNA sequence containing a series of codons that specify a particular protein. The variation that occurs between individuals in a population is a result sequence differences in specific genes. These sequence differences are often the result of mutations.

A mutation alters the sequence of nucleotide bases in a DNA molecule. This in turn alters the transcribed RNA, creating a different codon. Some mutations, because of the redundancy described above, are silent, meaning that if the mutation results in a base change that creates a codon for the same amino acid (i.e., GGA to GGC) as specified by the original DNA sequence, there is no change in protein structure or function. However, if the mutation results in a different amino acid, or the creation of a stop codon, the change in protein structure and function can be deleterious. At each gene locus, an individual carries two alleles, one from each parent. An allele is defined as the DNA sequence at a given gene's location on the chromosome. If an individual has two identical alleles, that individual is said to have a homozygous genotype. If an individual has two different alleles, that individual is said to have a heterozygous genotype. The phenotype of each individual with regard to a specific gene is the outward, physical manifestation of a given genotype. That outward physical manifestation might be something immediately obvious in a given individual such as eye color, or it may not be apparent until a particular drug is administered to that individual.

Variations in a given gene may be present rarely in a population, or in relatively large numbers in a population. Polymorphisms are defined as genetic variations occurring at a frequency of 1% or greater in the population (species of interest). In humans, many of the genes encoding cytochrome P450 enzymes are polymorphic (specific mutations are present in greater than 1% of the population), whereas some inherited human diseases such as cystic fibrosis are caused by rare mutations occurring in less than 1% of the population. For some diseases, identification of a specific mutation may be used to provide specific treatment approaches for the patient and, in the case of veterinary patients, guide breeding decisions as well. However, many common diseases in human patients, such as diabetes mellitus and many cardiovascular disease, are polygenic (more than one gene contributes to the disease). For diseases that are polygenic in nature, the pathophysiology of the disease is complex, and specific treatments based on particular mutations will be difficult to sort out. It is likely that many important diseases in veterinary medicine (i.e., hip dysplasia, epilepsy, most types of cancer) are polygenic also.

Pharmacogenetics

Genetic variation can affect both the pharmacokinetics (i.e., drug absorption, distribution, metabolism, and excretion) and pharmacodynamics (i.e., interaction with drug transporters and receptors) of pharmaceutical agents. The concept of pharmacogenetics originated in the 1950s when it was discovered that the antimalarial drug primaquine caused hemolysis in a subpopulation of individuals (Hochstein, 1971). Ultimately, it was shown that the enzyme glucose 6-phosphate dehydrogenase had reduced function in affected individuals as compared to the majority of the population (Hochstein, 1971). At the time, techniques to study molecular biology were not available, so the field of pharmacogenetics was initially based purely on phenotypic observations (measurement of enzyme function). Discovery of the specific mutation in the glucose 6-phosphate dehydrogenase gene would not occur until a few decades later.

With the rapid advancement of molecular techniques, modern pharmacogenetic research differs significantly from those initial phenotypic observations. It currently involves identifying both the phenotype and the genetic variation responsible for it. Researchers perform systematic searches to identify functionally significant variations in DNA sequences in genes that affect drug disposition. In many instances, the genetic variation in a gene is identified before the phenotypic consequence is known. The availability of published sequences for the canine genome, feline genome, and genomes of other veterinary species has accelerated the progress of pharmacogenetic discoveries, facilitating the ultimate goal of pharmacogenetics, which is individualization of drug therapy.

It is important to note that individualization of drug therapy encompasses two distinct, yet equally important, clinical implications. First is the ability to predict those patients at high risk for developing drug toxicity. These patients may have a mutation in a drug-metabolizing enzyme that decreases drug clearance. For such patients a lower drug dose, longer dosing interval, or alternate drug should be administered. Second is the ability to predict those patients that are most likely to benefit from a particular drug because of appropriate receptor interactions. Patients with mutations in drug receptors may be poor responders to certain pharmaceutical agents. Rather than using a trial-and-error approach to drug therapy, a veterinarian could select the drug most likely to produce the desired pharmacological response in a particular patient, decreasing the amount of time in which the patient's disease state is poorly controlled.

Described in this chapter are several recent discoveries in veterinary pharmacogenetics and examples of pharmacogenetically based differences in drug absorption, distribution, metabolism, excretion, and drug–receptor interactions. The fundamentals of these topics were extensively discussed in Chapters 2, 3 and 4. The impact of these discoveries in clinical veterinary medicine will also be presented.

Pharmacogenetics of Oral Drug Absorption

Systemic bioavailability of orally administered drugs is often considered to be a function of physicochemical characteristics of the drug and subsequent hepatic metabolism. A number of other factors have recently been shown to impact the ability of a drug to be absorbed into the systemic circulation after oral administration. Intestinal Phase I drug metabolism and active drug extrusion by efflux transporters are now considered to be among the most important determinants of oral drug bioavailability. Consequently, genetic variation in intestinal drug metabolizing enzymes and drug transporters as well as hepatic drug metabolizing enzymes and transporters is likely to dramatically affect oral drug absorption.

In people, CYP3A is expressed at higher levels in mature villus tip enterocytes than in hepatocytes (Patel and Mitra, 2001). Because intestinal villi comprise such a large surface area, there is a high likelihood that absorbed drug will interact with intestinal CYP3A enzyme, facilitating substantial first-pass metabolism. Interpatient variability in intestinal CYP3A levels has been studied in a small sample of human patients. Elevenfold variations in CYP3A protein content and sixfold variation in enzymatic activity were identified, suggesting that CYP3A polymorphisms exist in the human population (Scordo and Spina, 2002). While intestinal drug metabolism is thought to be important in veterinary patients also, relatively little is known with regard to interpatient variability in enzyme activity.

Drug transporters are also known to play an important role in drug absorption. Many drug transporters have been identified in people, but the most well-characterized drug transporter is P-glycoprotein (P-gp), the product of the *MDR1* (also known as the *ABCB1*) gene. The potential impact of transporter pharmacogenetics on drug pharmacokinetics is dramatically illustrated by P-gp. P-gp is a transmembrane protein that was first described in highly resistant tumor cell lines (Roninson, 1992). Tumor cells expressing P-gp were cross-resistant to various anticancer agents (anthracyclines, vinca alkaloids, taxanes, and others). P-gp has since been shown to act as an ATP-dependent pump that exports drugs from nonneoplastic cells as well. In normal mammalian tissues, P-gp appears to function in a protective capacity. P-gp is expressed on bile canaliculi, renal tubular epithelial cells, the placenta, brain capillary endothelial cells, and at the luminal border of intestinal epithelial cells (Thiebaut et al., 1987). At these locations, P-gp pumps selected drugs either out of the body (into the bile, urine, or intestinal lumen) or away from protected sites (brain tissue, fetus).

The significant role intestinal P-gp can play in determining oral drug bioavailability has been demonstrated in rodent studies. In *mdr1* (−/−) knockout mice, oral bioavailability of many P-gp substrate drugs (vinblastine, taxol, digoxin, loperamide, ivermectin, cyclosporine A, and others) is substantially greater than in wild-type mice (Schinkel et al., 1995; Sills et al., 2002). Similarly, *MDR1* polymorphisms in people have been shown to result in altered oral bioavailability of P-gp substrate drugs. Studies have shown that oral bioavailability of digoxin, a P-gp substrate, is greater in subjects with the *MDR1* 3435TT genotype compared with those with the *MDR1* 3435CC genotype (Verstuyft et al., 2003). The P-gp substrate phenytoin has also been shown to have lower oral bioavailability in subjects with the *MDR1* 3435CC genotype (Kerb et al., 2001).

P-gp has been fairly well characterized in dogs. The tissue distribution of P-gp in dogs is similar to that in people (Ginn, 1996), and it has been shown to contribute to chemotherapeutic drug resistance in vitro and in vivo (Mealey et al., 1998; Page et al., 2000; McEntee et al., 2003). Its role in determining oral drug bioavailability in dogs has been characterized only indirectly until recently. The indirect evidence to support that P-gp is important in oral drug absorption in dogs was generated from studies using P-gp inhibitors. Bioavailability of the anticancer agent (and P-gp substrate) docetaxel was increased 17-fold when coadministered with a P-gp inhibitor (McEntee et al., 2003).

More recently, P-gp's role in oral drug absorption was investigated in dogs affected by an important polymorphism of the *MDR1* (*ABCB1*) gene. This polymorphism consists of a four-base-pair deletion mutation (*ABCB1-1*Δ). This deletion results in a shift of the reading frame that generates several premature stop codons (Mealey et al., 2001). Because protein synthesis is terminated before even 10% of the protein product is synthesized, dogs with two mutant alleles exhibit a P-gp null phenotype, similar to *mdr1* (−/−) knockout mice. Affected dogs include many herding breeds. For example, roughly 75% of collies in the United States, France, and Australia have at least one mutant allele (Mealey et al., 2002). Other affected herding breeds, albeit at a lower frequency, include Old English Sheepdogs, Australian Shepherds, Shelties, English Shepherds, Border Collies, German Shepherds, Silken Windhounds, McNabs, and Long-haired Whippets (Neff et al., 2004).

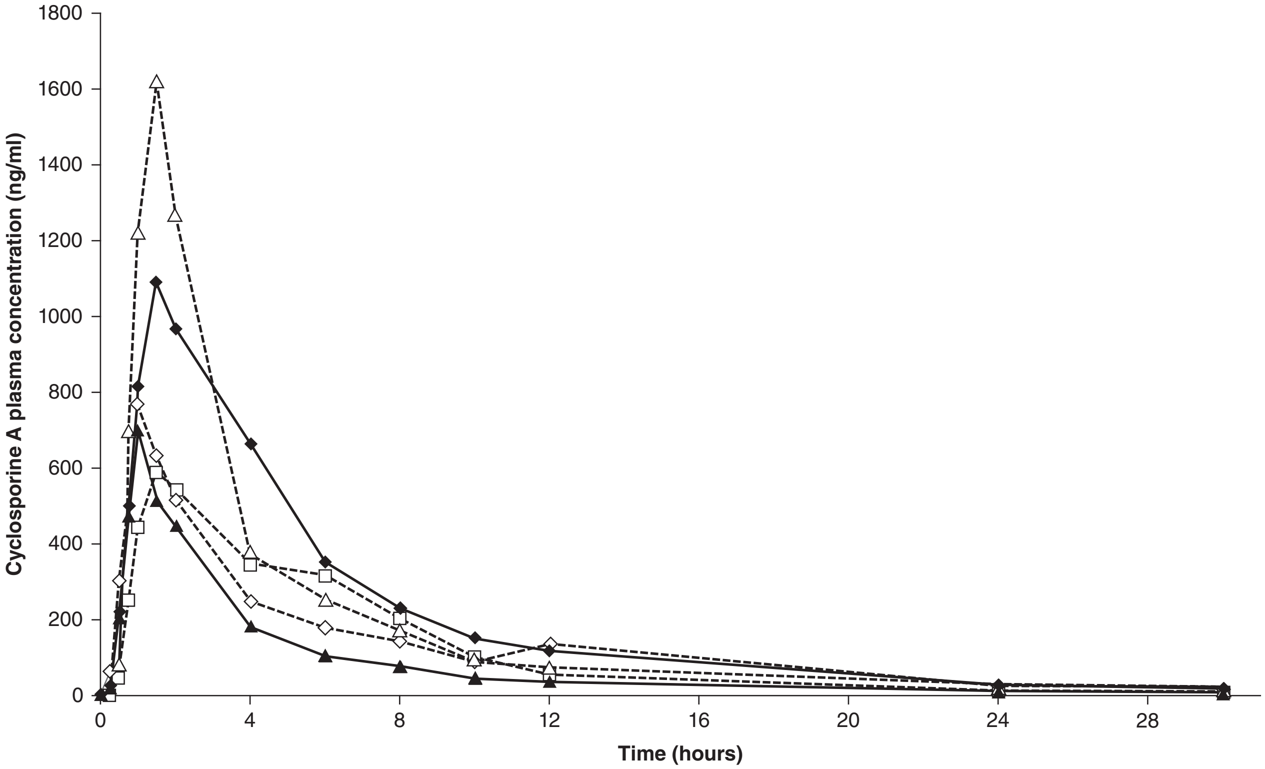

Figure 50.1 Plasma concentration versus time curves of cyclosporine after oral administration (4 mg/kg) to *MDR1* mutant/mutant (open symbols, dashed lines; n = 3) and *MDR1* normal/normal (closed symbols, solid lines; n = 2) Collie dogs.

Oral bioavailability of several P-gp substrates (quinidine, loperamide, nelfinavir, and cyclosporine) were determined in *MDR1* mutant/mutant and *MDR1* normal/normal dogs (Figure 50.1). Contrary to what appears to be the case in other species, there were no differences in oral bioavailability between *MDR1* mutant/mutant dogs and *MDR1* normal/normal dogs for any of the drugs studied (Mise et al., 2004). There are several explanations for the apparent discordant results. First, many P-gp substrates are also CYP3A substrates. Variable CYP3A activity in the study population could have masked differences in P-gp-mediated drug absorption. Second, there may be species differences in P-gp substrate binding and/or efflux kinetics such that oral drug bioavailability is impacted in one species with deficient intestinal P-gp function but not in another. For example, rodents have two genes that encode for P-gp (*abcb1a* and *abcb1b*) while dogs have only one (*ABCB1*). Lastly, at concentrations of drug achieved in the intestine after oral drug administration, P-gp may simply be saturated.

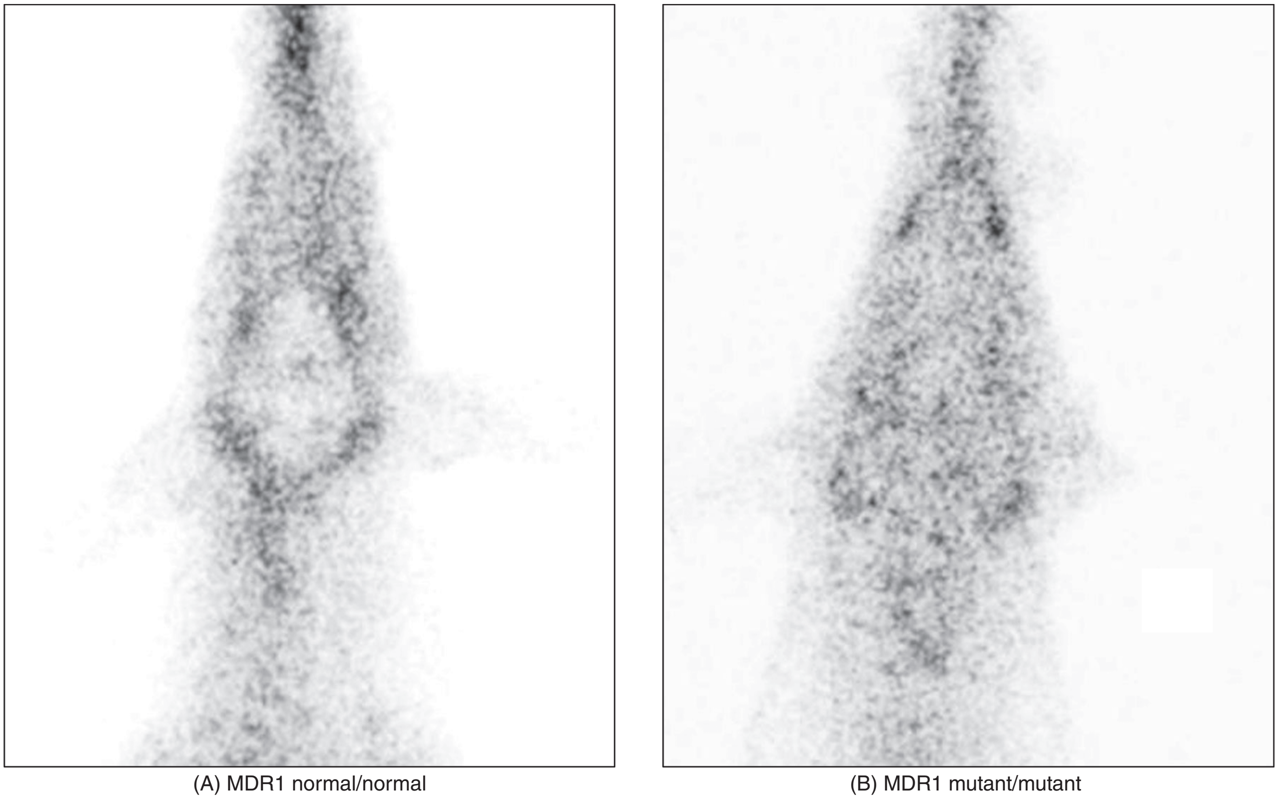
P-glycoprotein is not the only drug transporter that has been shown to affect oral drug absorption in humans and rodents. The breast cancer resistance protein (BCRP), encoded by the *ABCG2* gene, affects oral bioavailability of several drugs in *abcg*2 knockout mice and/or human patients with functional *ABCG2* polymorphisms. Patients with an *ABCG2* variant that alters amino acid 141 have greater oral bioavailability of topotecan than patients with the wild-type allele. Similarly, this variant is associated with greater oral bioavailability of rosuvastatin. Domestic cats, compared to 10 other mammalian species, have defective *ABCG2* function as a result of an *ABCG2* variant that alters amino acid 149 (Court, 2013b). Whether or not this variant affects oral absorption of ABCG2 substrate drugs is not yet known.

Pharmacogenetics of Drug Distribution

Drug distribution, the delivery of drugs from the systemic circulation to tissues, can be dramatically affected by pharmacogenetics. The drug transporter P-gp serves as an important barrier to the distribution of substrate drugs to selected tissues. For example, P-gp is a component of the blood–brain barrier, the blood–testes barrier, and the placenta. Therefore, distribution of P-gp substrate drugs to these tissues is greatly enhanced in dogs with the *MDR1* deletion mutation. Dogs homozygous for the deletion (*MDR1* mutant/mutant) experience adverse neurological effects after a single dose of ivermectin (120 μg/kg). Heterozygous (*MDR1* wild-type/mutant) or homozygous wild-type dogs are not sensitive to ivermectin neurotoxicity at the 120 μg/kg dose, but heterozygote animals may experience neurotoxicity at ivermectin doses greater than 300 μg/kg, particularly if daily doses are administered (i.e., protocols for treatment of demodectic mange). Dogs homozygous for the normal *MDR1* allele (*MDR1* normal/normal), can receive 2000 μg/kg as a single dose without signs of toxicity, and can receive 600 μg/kg/day for months without signs of toxicity. Dogs with the *MDR1* mutation also appear to have increased susceptibility to neurological adverse effects of other avermectins, including milbemycin, selamectin (Revolution® package insert), and moxidectin (Tranquilli et al., 1991). Interestingly, a retrospective study conducted by a national veterinary poison center reported that Collies (the breed with the highest frequency of the *MDR1* mutation) were overrepresented in canine cases of loperamide-induced neurotoxicity (Hugnet et al., 1996). Many Collies displayed signs of neurological toxicity after administration of routinely recommended doses of the antidiarrheal agent loperamide (Imodium®). Loperamide is an opioid that is generally devoid of CNS activity because it is excluded from the brain by P-gp (Ericsson and Johnson, 1990; Wandel et al., 2002). One study demonstrated that dogs with the *MDR1* mutation experienced marked CNS depression after loperamide administration whereas *MDR1* normal/normal dogs experienced no CNS depression (Court et al., 1999).

Figure 50.2 dramatically illustrates P-gp's ability to limit substrate accumulation within the CNS. *MDR1* mutant/mutant and *MDR1* normal/normal dogs received a single intravenous dose of ^{99m}Tc-sestamibi, a radiolabeled P-gp substrate. Nuclear scintigraphy demonstrated minimal uptake of radioactivity in the brain of *MDR1* normal/normal dogs because P-gp actively effluxes the substrate. Sensitive brain tissue is therefore protected from potentially toxic compounds. Conversely, uptake of radioactivity in the brain of *MDR1* mutant/mutant dogs is indistinguishable from surrounding tissues, illustrating the importance of P-gp as a component of the blood–brain barrier (Court et al., 1999). Brain tissue is exposed to much higher concentrations of potentially toxic compounds.

Less information is available regarding P-gp and the blood brain–barrier in cats. The author has recently investigated the feline *ABCB1* gene in cats that experienced ivermectin toxicity after receiving standard doses. A mutation was discovered that would severely impact P-gp function in affected cats (manuscript in preparation). The prevalence of this mutation in the general cat population is estimated to be approximately 5%. Cats affected by this mutation would be expected to



(A) MDR1 normal/normal

(B) MDR1 mutant/mutant

Figure 50.2 Nuclear scintigraphy was used to image the head of two Collies after intravenous injection of the P-gp substrate ^{99m}Tc-sestamibi. The MDR1 normal/normal dog (A) with functional P-gp has prevented accumulation of labeled substrate in the brain, while the MDR1 mutant/mutant dog (B) with defective P-gp function has accumulated the P-gp substrate within brain tissue (Mealey et al., 2008).

have the same phenotype (drug sensitivity) as dogs with the *MDR1* mutation.

Distribution of substrate drugs to the testes and fetus is also limited by P-gp. In human patients, this hampers effective treatment for certain diseases. For example, the testes and brain are considered to be a sanctuary site for the human immunodeficiency virus (HIV)(Choo et al., 2000). Because HIV-1 protease inhibitors are substrates for P-gp, the virus can remain viable in these sanctuary sites, hampering effective therapy. Similarly, therapeutic concentrations of certain chemotherapeutic agents may not be achievable for testicular cancers because of active efflux by P-gp (Katagiri et al., 1993). The effect of placental P-gp on distribution of drugs to the fetus is an area of active research in human medicine (Young et al., 2003). Understanding the role of pregnancy-related hormones in regulating P-gp expression and function is one possible key in developing strategies to deliver drugs to the mother with minimal fetal risk.

Another important drug transporter, briefly mentioned in Section Pharmacogenetics of Oral Drug Absorption, also plays a key role in drug distribution. ABCG2, also known as BCRP, has been studied in several veterinary species including sheep (Polido et al., 2006), cattle (Olsen et al., 2007), and cats (Ramirez et al., 2011). ABCG2 functions as a drug efflux pump in a variety of tissues including the liver, intestine, blood–brain barrier, blood–retina barrier, and mammary gland. ABCG2 dramatically affects concentrations of substrate drugs such as fluoroquinolones in milk (Jonker et al., 2005). A polymorphism in bovine ABCG2 (Tyr581Ser) increases secretion of danoflaxoacin into milk (Otero et al., 2013). After an intramuscular dose of danofloxacin, the AUC and C_{max} of danoflloxacin in milk were twofold lower in cattle with the wild-type *ABCG2* genotype compared to cattle with the *ABCG2* polymorphism. Other fluoroquinolones have also been shown to be actively secreted into milk by ABCG2. Thus, polymorphisms in ABCG2 have implications for drug residues in milk as well as for treatment of mastitis.

Feline ABCG2 has several amino acid changes compared to 10 other mammalian species. One of the amino acid changes is similar to a human variant (ABCG2 421C>A) that results in defective ABCG2 function in people. Feline ABCG2 has decreased ability to transport the “gold-standard” ABCG2 substrate mitoxantrone compared to both human and canine ABCG2 (Ramirez et al., 2011). This has important clinical implications, particularly when one considers that these amino acid changes appear to affect all cats. Consequently, cats would be expected to exhibit enhanced sensitivity to ABCG2 substrate drugs compared to other species.

This is obviously the case with certain fluoroquinolones. Domestic cats experience an unusual, and apparently species-specific, adverse drug reaction associated with fluoroquinolones – acute retinal degeneration and blindness (Wiebe and Hamilton, 2002). Fluoroquinolone-induced retinal toxicity was first documented with enrofloxacin, which is structurally similar to the human-approved fluoroquinolone ciprofloxacin. In a prospective study, 100% of cats that received enrofloxacin (10 × label dose) developed retinal degeneration as early as 3 days after treatment while 0% of control cats developed retinal lesions (Ford et al., 2007). Orbifloxacin, another fluoroquinolone approved for use in cats and dogs, also causes retinal damage in cats (FDA, 2006). Retinal degeneration and blindness can result from extensive phototoxic damage to the retina. When exposed to light, fluoroquinolones generate reactive oxygen species (ROS) that attack cellular lipid membranes causing tissue damage (Agrawal et al., 2007). Under normal conditions, the retina is protected from photoreactive compounds by the blood–retina barrier, including transporters such as ABCG2 that function to prevent distribution of xenobiotics to the retina (Asashima et al., 2006). As substrates for ABCG2, fluoroquinolone distribution to the retina is normally restricted by ABCG2. Dysfunction of ABCG2 in cats disrupts the blood–retina barrier, allowing accumulation of photoreactive fluoroquinolones. Exposure of the retina to light then generates ROS that damage tissues resulting in retinal degeneration and blindness.

The impact of feline ABCG2 dysfunction on other ABCG2-substrate drugs has not yet been investigated. Whether or not ABCG2 polymorphisms exist in other common veterinary species such as dogs or horses has not yet been documented.

Pharmacogenetics of Drug Metabolism

Presently, the greatest body of knowledge with regard to pharmacogenetics in human patients involves genetic variation in drug metabolizing enzymes. Pharmacogenetic variation can affect both Phase I and Phase II metabolic enzyme activity. A mutation in the gene encoding pseudocholinesterase serves as an example of how pharmacogenetic variation can result in dramatic differences in drug response between patients. Patients with a normal pseudocholinesterase genotype metabolize succinylcholine and recover from neuromuscular blockade rapidly; those with the mutant genotype undergo sustained neuromuscular blockade that can result in prolonged apnea and the necessity for mechanical ventilation (Wing, 1974). A number of polymorphisms have been described in human cytochrome P450 (CYP) enzymes, many of these resulting in profound variations in clinical response. For example CYP2D6 is a highly variable P450 pathway in humans with individuals ranging from undetectable activity (found in 6–10% of Caucasians) to “ultrarapid” activity (found in 3–10% of Europeans and 30% of one black population)(Cascorbi, 2003). The ultrarapid phenotype is due to a highly unusual gene duplication. Drugs that are substrates for CY2D6 in people include β-receptor antagonists (propranolol, timolol, metoprolol), antiarrhythmics (quinidine, flecainide), antidepressants (amitriptyline, clomoipramine, fluoxetine, imipramine), neuroleptics, and certain opioid derivatives. Depending on the patient's CYP2D6 genotype, the "typical" dose of a substrate drug may need to be decreased (poor metabolizers require 1/10 of the standard dose of nortriptyline to avoid toxicity) or increased (ultrarapid metabolizers require five times the standard dose to achieve therapeutic concentrations).

Canine CYP1A2

Compared to people, relatively few polymorphisms in drug metabolizing enzymes have been described in veterinary species. However, several polymorphisms have now been described in canine CYPs. The most well-characterized canine CYP polymorphism is a mutation (c1117C>T) in the coding region of *CYP1A2* that generates a premature stop codon. Homozygously affected dogs lack hepatic CYP1A2 protein expression and enzymatic function (Tenmizu et al., 2004; Mise et al., 2004).

Screening for the polymorphism in populations of beagles in Japanese research institutes identified approximately 11–17% of the dogs as homozygous for the mutant genotype and consequently lacking functional CYP1A2. Plasma concentrations of investigational drugs were up to 17 times greater in dogs with deficient CYP1A2 (Tenmizu et al., 2004; Mise et al., 2004). Plasma drug concentrations in dogs that were heterozygous for *CYP1A2* c1117C>T were not substantially different from concentrations in wild-type dogs. Whether or not this polymorphism impacts the pharmacokinetics, efficacy, and safety of clinically used drugs is not known and would depend on: (i) the presence of *CYP1A2* 1117C>T in the general canine patient population; and (ii) the degree to which a drug depended on CYP1A2 for clearance. A review article summarized the results of several studies investigating the allele frequency of *CYP1A2* 1117C>T (Court, 2013a). Breeds with the highest allele frequency include Irish Wolfhounds, Beagles, and Berger Blanc Suisse. Importantly, Beagles from Japan had a much higher allele frequency than Beagles from either Europe or the United States. Many of the remaining breeds that were found to harbor the mutation, albeit at allele frequencies <10% were the same herding breeds that are known to harbor *ABCB1-1*Δ, the mutation that results in P-gp deficiency.

Canine CYP2B11

A phenotype involving anesthetic sensitivity has been described for Greyhounds and other sighthound breeds. Specifically, dogs of this breed have been reported to have prolonged recovery from the injectable anesthetic agents including thiopental, thiamylal, and propofol. Many years ago this was attributed to decreased drug redistribution from the central compartment due to the lean nature of the affected breeds. Subsequently, researchers have identified decreased drug clearance in these dogs that was preventable by pretreating the dogs with the CYP inducer phenobarbital, implicating CYP involvement. Studies using dog liver microsomes identified CYP2B11 as the primary enzyme responsible for CYP-dependent clearance of propofol (Court et al., 1999; Hay Kraus et al., 2000). A specific molecular mechanism for this breed-dependent difference in drug disposition has not yet been reported.

Miscellaneous Canine CYP Polymorphisms

A canine CYP2C isoform, CYP2C41, was identified in a small percentage of beagles and mixed breed dogs suggesting that the majority of dogs have a partial or complete deletion of this enzyme. The CYP2C21 isoform was expressed in all dogs examined and because this isoform metabolizes many of the same drugs as CYP2C41, the impact of the canine CYP2C41 deletion on drug disposition may be minimal (Court, 2013a). Amino acid variants, likely the result of SNPs, involving canine CYP2D15, CYP2E1, and CYP3A12, have been reported. Further investigation is required to determine the allele frequency and the potential impact these variants might have on the disposition of various drugs in the clinical setting.

CYP Polymorphisms in Other Species

A feline hepatic CYP2E polymorphism has been identified, but the clinical relevance of this polymorphism has not been described (Tanaka et al., 2005). Similarly, polymorphisms have been described in several drug-metabolizing enzymes in cattle (Theilmann et al., 1989), but these single nucleotide polymorphisms are used as molecular markers available in cattle for linkage analysis, testing of parentage, and distinction of breeds, rather than for predicting response to drug therapy.

Phase II Metabolic Enzymes

With respect to Phase II metabolic enzymes, a panspecies defect in UDP-glucuronyl transferase (UGT) enzymes exists in cats and these defects dramatically affect drug disposition in that species. Because these defects represent a genetic variation between species rather than within a species, these are not considered true pharmagenetic defects. Cats lack several, but not all, UGTs. The UGTs lacking in cats are responsible for metabolizing simple planar phenolic compounds (e.g., acetaminophen and other phenolic compounds) (Court, 2013b). This defect partially explains the pharmacological idiosyncrasies of cats relative to most common veterinary species.

Another panspecies Phase II metabolic defect occurs in dogs. *N*-acetyltransferase is the enzyme responsible for metabolizing sulfonamides, procainamide, hydralazine, and other drugs. Both *N*-acetyltransferase genes (*NAT1* and *NAT2*) are absent in dogs, increasing the risk for hypersensitivity reactions and adverse effects from these drugs relative to other species (Trepanier et al., 1997). *NAT2* deficiency contributes to low clearance of some sulfonamides. Cats lack *NAT2* but express *NAT1* (Court, 2013b).

A true pharmacogenetic variation exists for the thiopurine methyltransferase (TPMT) enzyme. TPMT is a Phase II enzyme that is responsible for metabolizing azathioprine and its active metabolites to their inactive forms. A ninefold range in TMPT activity exists in dogs, and enzyme activity level appears to be related to breed. Giant Schnauzers had lower TPMT activity while Alaskan Malamutes had high TMT activity (Kidd et al., 2004). Decreased TPMT activity has been documented to be associated with increased susceptibility to azathioprine-induced bone marrow suppression.

Pharmacogenetics of Drug Excretion

Drugs are eliminated from the body either unchanged or as metabolites. Renal and biliary excretion are the most important pathways of drug elimination, but excretion may occur by other routes as well.

P-glycoprotein Mediated Biliary Excretion

As noted previously, P-gp is expressed on renal tubular cells and biliary canalicular cells, suggesting that it may play a role in drug excretion. The *ABCB1-1*Δ mutation dramatically impacts biliary drug excretion. Studies using the radiolabeled P-gp substrate $^{99\mathrm{m}}$Tc-sestamibi in *MDR1* mutant/mutant and *MDR1* normal/normal dogs illustrate the importance of P-gp-mediated biliary excretion of compounds that are P-gp substrates. *MDR1* mutant/mutant dogs have significantly decreased biliary excretion of $^{99\mathrm{m}}$Tc-sestamibi compared to *MDR1* normal/normal dogs (Coelho et al., 2009). *MDR1* mutant/normal dogs have an intermediate phenotype. *MDR1* mutant/mutant dogs appear to have no biliary excretion of $^{99\mathrm{m}}$Tc-sestamibi (Figure 50.3). Thus, blood and tissue concentrations of P-gp substrates are likely to persist longer in *MDR1* mutant/mutant dogs compared to *MDR1* normal/normal dogs, increasing the risk for adverse drug reactions. Because clearance of both vincristine and doxorubicin depend on P-gp mediated biliary excretion, these drugs serve as examples of P-gp substrate drugs that carry a higher risk for toxicity in *MDR1* mutant/mutant dogs compared to *MDR1* normal/normal dogs.

A prospective study examined vincristine-associated hematological toxicity in dogs with lymphoma. Dogs that were either heterozygous or homozygous for *ABCB1-1*Δ were significantly more likely to develop neutropenia and thrombocytopenia than wild-type dogs (Mealey et al., 2008). The author is aware of two *MDR1* mutant/mutant dogs that died from complications of sepsis after receiving doxorubicin (30 mg/m^2). Both dogs experienced severe GI toxicity and severe neutropenia within 10 days of receiving doxorubicin. Initiating a prospective study to specifically define the effects of doxorubicin in dogs with the *MDR1* mutation was not pursued for obvious ethical reasons. Other reports of severe doxorubicin, vinblastine, and/or vincristine sensitivity in Collies and other herding breeds have surfaced on internet veterinary discussion groups. Thus, genotyping herding breed dogs and mixed breed dogs prior to treatment with P-gp

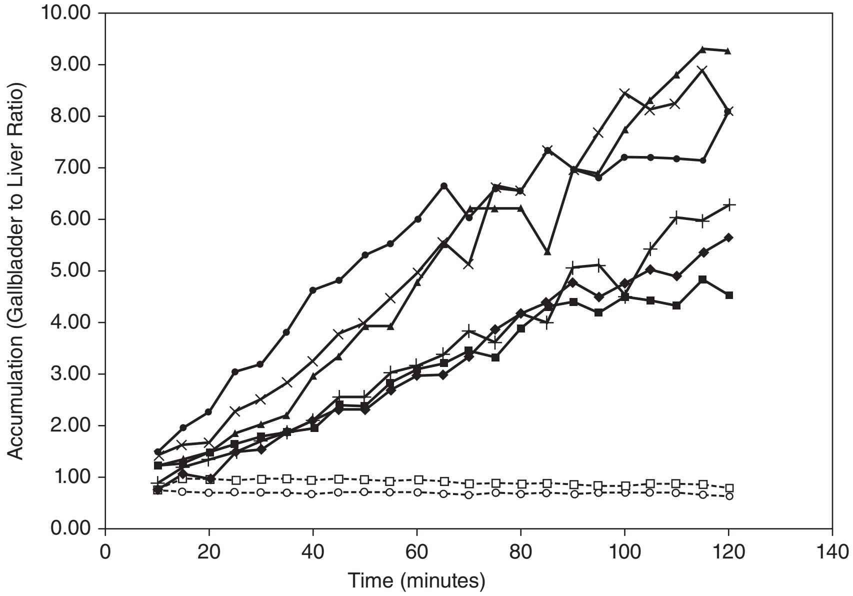


Figure 50.3 Accumulation of the P-gp substrate $^{99\mathrm{m}}$Tc-sestamibi over time in the gallbladder of six *MDR1* mutant/mutant (solid lines) and two *MDR1* normal/normal dogs (dotted lines) after intravenous injection of $^{99\mathrm{m}}$Tc-sestamibi. Note that *MDR1* mutant/mutant dogs are essentially unable to excrete P-gp substrates.

substrate chemotherapeutic drugs has become the standard of care in veterinary oncology. Based on the individual patient's *MDR1* genotype, appropriate dose reductions can be made so that the patient experiences the antitumor effect of these drugs but avoids severe toxicity.

Solute Carrier-Mediated Renal Excretion

The solute carrier (SLC) superfamily of transporters consists of both uptake transporters (transport substrates into cells) and efflux transporters (transport substrates out of cells). In humans and rodents, members of the SLC superfamily transport a variety of endogenous and exogenous compounds (Roth et al., 2012). There is some overlap of substrates among members of the SLC superfamily in humans and rodents. For example, fluvastatin (cholesterol-lowering drug) is a substrate for at least three different members of the human SLC superfamily. Less is known about substrate specificity of veterinary SLC transporters. In humans, rodents, and presumably other veterinary species, SLC transporters are expressed along the body's functional "barrier" tissues including intestine, brain capillary endothelial cells, placenta, liver, and kidney as well as other tissues. These strategic locations allow SLC transporters to influence not only renal drug excretion, but drug absorption, distribution, and metabolism as well. Members of the SLC superfamily include organic cation transporters (OCTs), multidrug and toxin extrusion transporters (MATEs), organic anion transporters (OATs), and organic anion transporting polypeptides (OATPs). Genetic variation in OCTs has been documented in human patients (Franke et al., 2010). Plasma concentrations of the antiemetic ondansetron are higher and clinical effects greater in human patients with *OCT1* mutations. The author is not aware of genetic variants in the SLC superfamily in veterinary species that have been associated with changes in drug disposition.

Pharmacogenetics of Drug Receptors

A more recently explored area of pharmacogenetics involves identifying polymorphisms in genes encoding drug receptors and effector proteins. In human patients, polymorphisms have been described in angiotensin converting enzyme (ACE), β-adrenergic receptors, the dopamine receptor, the estrogen receptor, and others (Tribut et al., 2002). One polymorphism in the *ACE* gene in patients with heart failure is associated with an increased risk of death or the need for transplantation (Joseph et al., 2014). Polymorphisms of the human β_1-adrenergic receptor (ADRB1) have been shown to have either enhancing or suppressing effects on adenylyl cyclase activity, depending on the particular polymorphism. Because effects of individual polymorphisms on clinical outcomes have not been conclusive, pharmacogenetic testing for ADRB1 polymorphisms has not been adopted into clinical cardiology practice.

Two independent in-frame deletion mutations have been described in canine ADRB1 (Maran et al., 2013). Preliminary results suggest that dogs that harbor both of these deletions are less responsive to the effects of the β-adrenergic antagonist atenolol. Polymorphisms of feline ADRB1 have also been described but the functional significance has not yet been determined (Maran et al., 2012).

A polymorphism in the canine phosphodiesterase 5A (*PDE5A*) gene has been described (Stern et al., 2014). Vasodilators such as nitric oxide and sildenafil interact with PDE5A. Plasma concentrations of cGMP were significantly lower in dogs with the PDE5A polymorphism compared to wild-type dogs. Whether or not affected dogs respond differently to nitric oxide or sildenafil has yet to be determined.

Pharmacogenetics and Idiosyncratic Reactions

Pharmacogenetic differences in metabolic pathways can affect not only Type A adverse drug reactions (predictable; generally correlating with plasma drug concentration), but can also affect type B adverse drug reactions (idiosyncratic). Idiosyncratic reactions are sometimes called hypersensitivity reactions but they do not always involve an adaptive immune response. One of the most common drug classes involved in idiosyncratic adverse reactions in both dogs and people are the sulfonamides and can be characterized by fever, arthropathy, blood dyscrasias (neutropenia, thrombocytopenia, or hemolytic anemia), hepatopathy consisting of cholestasis or necrosis, skin eruptions, uveitis, or keratoconjunctivitis sicca (Trepanier, 2004). In people, slow acetylation by NAT2 has been shown to be a risk factor for sulfonamide hypersensitivity reactions. It has been proposed that alternative metabolic pathway in these individuals generate reactive metabolites. Covalent binding of these reactive metabolites to cell macromolecules results in cytotoxicity and immune response to neoantigens. While a specific genetic variant or variants have not been identified in dogs experiencing sulfonamide hypersensitivity, a study has ruled out the sulfonamide detoxification genes *NAT2*, *CYB5A*, and *CYP5R3* (Sacco et al., 2012).

Pharmacogenetics and Protein Binding

Several plasma proteins can bind xenobiotics but albumin is usually considered to be among the most important with regard to drugs used in veterinary medicine. Because only the unbound fraction of drug is pharmacologically active, changes in protein binding can affect efficacy and toxicity of highly protein-bound drugs. The pharmacokinetics of a drug can also be altered with changes in the degree of protein binding. Since only the unbound fraction is generally available for metabolism and/or excretion, clearance of a highly protein-bound drug may be increased in situations that increase the unbound fraction of that drug. Situations that can alter protein binding of a drug for an individual patient include: drug interactions (coadministration of two highly protein-bound drugs); and changes in plasma albumin concentration (disease states causing hypoalbuminemia or rapid increases in plasma albumin resulting from administration of albumin solutions). Pharmacogenetics may account for differences in protein binding between patients.

For example, two linked SNPs (G1075T and A1422T) in the canine albumin gene were shown to correlate with protein binding and clearance of an investigative drug (Takashi et al., 2009). The SNPs results in an amino acid changes (Ala335Ser and Glu450Asp) that appear to alter binding of the investigative compound, an integrin antagonist. The prevalence of the mutant allele in a research beagle colony was 40% (n = 47). The drug is >99% protein bound in all dogs with the mean unbound fraction in homozygous wild-type beagles (0.014%), significantly lower than in beagles homozygous for the mutant allele (0.053%). Clearance of the drug was significantly greater in beagles homozygous for the mutant allele (3.66 ml/min/kg) than in beagles homozygous for the wild-type allele (1.97 ml/min/kg). For both measurements heterozygous beagles were intermediate. Further investigation is necessary to determine: (i) if this mutation is present in dogs (beagles and other breeds) outside this colony; and (ii) if other highly protein-bound drugs are affected by this allele.

Pharmacogenetics in Clinical Practice

Clinical use of pharmacogenetic testing for human patients is becoming standard practice for some drugs. In fact, pharmacogenetic testing is now required by the FDA for some drugs, and for others, the label includes information regarding genetic variations that impact the drug's use (Pacanowski et al., 2014).There are over two dozen pharmacogenetic tests available for human patients. Some of these pharmacogenetic tests may improve selection of patients for which a particular drug will be effective while others may predict which patients are more likely to experience an adverse reaction. Pharmacogenetic testing for oncological and cardiovascular drugs seems to be the most readily available. For example, pharmacogenetic testing is available for the anticancer drugs 5-fluorouracil, irinotecan, herceptin, and tyrosine kinase inhibitors and FLT3 inhibitors. Pharmacogenetic testing for the "blood thinners" clopidogrel and warfarin is also readily available. Pharmacogenetic testing for individual drug metabolizing enzymes (CYP2D6, CYP2C19, CYP3A4 and 5, NAT2, and others) is also available. Thus, it is possible for a physician to obtain a complete CYP profile on a patient. However, specific dosing recommendations are not currently available for most drugs despite knowing a patient's CYP profile, so the clinical applications of such testing may be limited.

In veterinary medicine, a commercial veterinary pharmacogenetics laboratory (Veterinary Clinical Pharmacology Laboratory, Washington State University, Pullman, WA, 99164; www.vetmed.wsu.edu/vcpl) is performing canine *MDR1* (*ABCB1-1*Δ) genotyping for veterinarians, dog breeders, and owners. Pharmacogenetic testing is considered standard-of-care for some canine patients. Dogs for which vincristine, vinblastine,

doxorubicin, loperamide, or ivermectin (extralabel dose for treating mange) are being considered should be tested for the *MDR1* mutation prior to dosing. See Table 50.1 for a partial list of drugs that are substrates for P-gp. Because the *MDR1* mutation in dogs has a very high allelic frequency (55% in Collies; 42% in Longhaired Whippets; and roughly 20% in Australian Shepherds), and because the polymorphism is highly predictive for serious adverse drug events including death, pharmacogenetic testing in dogs has been readily accepted by veterinarians.

Future Directions

The *MDR1* test for dogs demonstrates that the relatively new field of pharmacogenetics has already made an impact on drug safety and efficacy for veterinary patients. As is the case with any novel medical procedure, it will take time for pharmacogenetics to be considered a standard tool for making treatment decisions. Because the FDA already screens drugs for safety and efficacy in large patient populations, pharmacogenetics, by default, benefits a minority of the population. However, by using pharmacogenomics as a tool for making therapeutic decisions, veterinarians will be able to provide better overall treatment by optimizing therapy for each patient (choosing the right dose of the right drug the first time — rather than by trial and error). The ultimate goal of pharmacogenetics is to enable patients to respond to treatment faster, at less expense, and with a much lower risk for adverse effects.

Considerations for Treating Minor Food-Producing Animals with Veterinary Pharmaceuticals

Lisa A. Tell, Margaret Oeller, Tara Marmulak, and Ronette Gehring

The Use of Veterinary Pharmaceuticals in Minor Food-Producing Animals: Special Considerations and Challenges

Antibiotics, antiparasitics, nonsteroidal antiinflammatory drugs, and exogenous hormones are among the essential components in the armamentarium of a food animal veterinarian to combat disease, alleviate animal pain, and minimize economic losses. In the United States, many of these veterinary products are US Food and Drug Administration (FDA) approved for use in a large number of major food-producing animals but not for the minor food-producing animals. According to the FDA, the major food-producing animals are cattle (meat and milk), swine, chickens (meat and eggs), and turkeys. The minor food-producing animals are those that do not fall into the major food-producing animal category with the most popular being goats (both dairy and meat), sheep, deer, commercially raised game birds, and food fish and shellfish. This category also includes less obvious food-producing species such as rabbits, ratites, and honey bees. In the USA, horses are a major animal species; however, they are considered companion animals and are not customarily used for human food as in some other countries. In Europe, the European Medicines Agency has defined the major food-producing animals to be cattle (meat and milk), sheep (meat); pigs; chickens (meat and eggs), and salmonids. Minor food-producing animals include minor ruminants (meat and milk), deer (including reindeer), other avian species (meat and eggs), other fish species, and other mammalian species (horse and rabbit). In other countries, the minor food-producing animal category has the potential to be considerably larger because a greater variety of species are consumed such as small rodents, canids, invertebrates, and various avian species.

In recent years, there has been an increased interest in consuming more meat and other products from minor food-producing animals, especially aquaculture species. As this interest grows, so will the expectations to provide safe food items for human consumption. Maintaining the overall health of minor food-producing animals is similar to managing the health of major food-producing animals, and typically requires some use of veterinary pharmaceuticals. However, in contrast to the major food-producing animals, few drugs have FDA approval for use in minor food-producing animals.

One of the major challenges for getting veterinary products approved for use in minor food-producing animals is the reduced economic return due to small market size. Additionally, some of the minor food-producing animals are less tractable (e.g., cervids and bison), and there is wide variation in breeds/species with respect to size and pharmacokinetics. In general, there is a large number of species and incredible diversity within this category. For aquatic species, such as finfish, mollusks, and crustaceans, not only are there species differences, but environmental considerations (salinity, pH, temperature), physiological differences (heterothermy), and management practices that also impact metabolism and excretion of drugs.

This chapter addresses the unique issues associated with the regulatory requirements for getting a drug approved for use in a minor food-producing animal, the availability of veterinary pharmaceuticals for use in minor food-producing animals, and highlights legislation that has helped address the veterinarian's need for medications to treat these animals. In addition, government programs and scientific approaches used to meet the therapeutic needs for treating minor food-producing animals are discussed.

The Approval Process for Veterinary Pharmaceuticals for Use in Minor Food-Producing Animals

There are many veterinary pharmaceuticals marketed today that may be administered to minor food-producing animals. The ideal scenario for a veterinarian wanting to

treat a minor food-producing animal is having an FDA-approved drug labeled for the intended use in question. One example would be an anthelmintic approved for treating specific gastrointestinal parasites in sheep. This product will have been demonstrated to FDA's satisfaction to be safe for sheep, safe for the person administering the drug to the sheep, safe for anyone who later consumes meat from the treated sheep, and safe for the environment, both during the drug's use and its disposal. It will also have been shown to be effective for the labeled use and that it is consistently manufactured to standards of strength and purity. Such a product is labeled with intended uses, doses, and withdrawal times that are appropriate for use in sheep.

In contrast to the major food-producing animals, there are not many FDA-approved drugs labeled for use in minor food-producing animals. This is mainly because the development of new drugs for use in animals is a very expensive and time-consuming process, especially for drugs to be used in animals intended for human consumption, and the minor food-producing animal markets are too small to readily recover the pharmaceutical sponsor's investment. FDA-approved drugs for minor food-producing animals (as of July 2017) are summarized in Tables 51.1–51.5. There is also a searchable database of approved new animal drugs available on the FDA website. Please note that even if approved, a particular product may not be commercially available. This can be for a variety of reasons including closing of manufacturing facilities, or the discontinuation of less lucrative product lines when two companies merge.

For a drug to be approved for use in a minor food-producing animal, the sponsor must demonstrate to the satisfaction of the scientific reviewers at FDA's Center for Veterinary Medicine (CVM) that it is safe and effective for its intended use. CVM is the component of FDA responsible for the regulation of veterinary drugs, including the evaluation of such drugs prior to approval.

The information that a sponsor needs to present to support a New Animal Drug Application (NADA) includes the following as outlined in regulations published in the Code of Federal Regulations (21 CFR 514):

1) effectiveness for the proposed use;
2) safety to the target animal species (the animal species for which the drug is to be used);
3) human food safety (safety to consumers of meat, milk, or eggs derived from treated animals);
4) environmental safety;
5) manufacturing methods and controls;
6) all other information;
7) freedom of information (FOI) summary; and
8) product labeling.

These components are discussed in detail in Chapter 55 of this book. The FDA also provides a variety of guidance documents to assist sponsors in understanding the various requirements. Of particular note for sponsors seeking drug approval for a minor species use is *Guidance #61 FDA Approval of New Animal Drugs for Minor Uses and for Minor Species*. This document is being revised at the time of writing this chapter and will be published under the new title, *Special Considerations, Incentives, and Programs to Support the Approval of New Animal Drugs for Minor Uses and for Minor Species*. Guidance documents are available on the FDA website.

Compared to the drug approval process for major food-producing animals, the drug approval process is not significantly easier for products intended for use in a minor food-producing species. The same high standards must be met. However, there are a few advantages afforded to products intended for use in a minor food-producing animal. These include the possibility of a waiver from user fees, the ability to apply conclusions reached from the radiolabeled residue study in the major food-producing animal to the human food safety evaluation for the minor food-producing animal, the possibility of a categorical exclusion from the need to provide an environmental assessment, and the possibility that fewer sites will be needed for effectiveness clinical trials.

Legislation and Policies Supporting the Availability of Veterinary Pharmaceuticals in Minor Food-Producing Animals

Animal Medicinal Drug Use Clarification Act

The US Congress recognized the drug availability problem for both major and minor animal species when it passed the Animal Medicinal Drug Use Clarification Act (AMDUCA) in 1994 (Public Law No. 103–396; Monti, 2000). This law addressed the fact that FDA generally approves veterinary drugs for narrow intended uses. For example, a broad-spectrum antibiotic that would be safe and effective for the treatment of a wide variety of bacterial infections may only be *approved* for use in cattle for the treatment of respiratory disease caused by specific bacteria. From a practical standpoint, the pharmaceutical sponsor cannot demonstrate safety and effectiveness for every possible intended use of the product. This means that veterinarians frequently administer the drug for indications that are not on the label. In other words, they use the drug for different diseases, at different doses, by different routes of administration, and in different animal species than what is indicated on the label.

AMDUCA legalized this practice for veterinarians within a set of limitations described in the Code of Federal Regulations (21 CFR 530). In general, veterinarians, within the context of a valid veterinarian–client–patient

relationship, may use approved dosage form products (but not medicated feeds) outside their labeling. This is allowed only when there is no approved drug for the intended use; other approved drugs are not effective for such use, when the dose is not effective for that use, or in cases where an approved formulation is not appropriate. When using a drug outside of its labeling for a food-producing animal, the veterinarian is responsible for using the drug in a manner that will not result in a violative residue in any food product derived from that animal. The veterinarian must establish a withdrawal period based on some scientific information, although

Xylazine hydrochloride	Injectable—IM, IV	Deer Elk	Sedation
Yohimbine hydrochloride	Injectable—IV	Deer Elk	Xylazine antagonist

[a] Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

there are few resources for establishing such times. The withdrawal period may be based on data in published literature, extrapolated from the pharmacokinetic profile of the drug, or determined through consultation with organizations such as the Food Animal Residue Avoidance and Depletion Program (FARAD). There are also certain drugs not eligible for extralabel use in food-producing animals. These are listed in the CFR at 530.41. This list includes a fairly new ban on the extralabel use of most cephalosporins. This ban applies only to the major species – cows, pigs, chickens, and turkeys.

Compliance Policy Guide 615.115

Because the extralabel use of medicated feeds is prohibited by law, an undue hardship was placed on minor food-producing animals that could not be practically medicated in any other way. An example would be commercially raised game birds, such as pheasants, that are raised in very large outdoor pens. If these birds become ill, they cannot be dosed individually and they will drink water from puddles rather than medicated water. Therefore, they are most often treated via the feed. Aquaculture species are another group of animals best treated with medicated feed. Given that there are few drugs approved for these species (and some of these not marketed) a means of relief was provided through a compliance policy guide (CPG). This CPG is FDA's direction to field investigators when and how to exercise enforcement discretion in these cases. The CPG does not make extralabel use of medicated feed legal and a CPG can be rescinded at any time. It simply means that if veterinarians, feed mills, and producers follow the parameters laid

Table 51.3 Veterinary pharmaceuticals approved by the Food and Drug Administration as of July, 2017 for use in avian species that are considered minor food-producing animals in the United States of America

Drug	Formulation	Species	Indication[a]
Amprolium	Premix (for feed)	Pheasants	Coccidiosis
Bacitracin methylene disalicylate	Premix (for feed)	Pheasants Quail	Weight gain/feed efficiency
Bacitracin methylene disalicylate	Water-soluble powder	Quail	Ulcerative enteritis
Bacitracin zinc	Premix (for feed)	Pheasants Quail	Weight gain/feed efficiency
Bacitracin zinc	Water-soluble powder	Quail	Ulcerative enteritis
Carnidazole	Tablets	Pigeons	Trichomoniasis
Chlortetracycline	Premix (for feed)	Ducks	Fowl cholera
Iodinated casein	Premix (for feed)	Ducks	Weight gain/feathering
Lasalocid	Premix (for feed)	Partridge (Chukar)	Coccidiosis
Monensin sodium	Premix (for feed)	Quail (Bobwhite)	Coccidiosis
Novobiocin	Premix (for feed)	Ducks	Bacterial infection
Salinomycin sodium	Premix (for feed) Powder	Quail	Coccidiosis
Sulfadimethoxine ormetoprim	Premix (for feed)	Ducks Partridge (Chukar)	Bacterial infection Coccidiosis
Thiabendazole	Premix (for feed)	Pheasants	Gapeworm

Table 51.4 Veterinary pharmaceuticals approved by the Food and Drug Administration as of May, 2014 for use in aquaculture species in the United States of America

Drug	Formulation	Species	Indication[a]
Florfenicol	Premix (for feed)	Catfish	Enteric septicemia of catfish
Florfenicol (now fully approved)	Premix (for feed)	Catfish	Columnaris disease
Florfenicol	Premix (for feed)	Freshwater-reared Salmonids	Coldwater disease Furunculosis
Florfenicol	Premix (for feed)	Freshwater-reared finfish	Streptococcal septicemia Columnaris disease
Formalin	Water treatment	Finfish eggs Shrimp (Penaeid)	Antiprotozoal Antifungal
Human chorionic gonadotropin	Injection	Finfish (male and female broodstock)	Spawning aid
35% Hydrogen peroxide	Water treatment	Freshwater-reared Salmonids	Bacterial gill disease
35% Hydrogen peroxide	Water treatment	Freshwater-reared finfish eggs	Saprolegniasis
35% Hydrogen peroxide	Water treatment	Freshwater-reared cool water finfish and channel catfish	External columnaris disease
Oxytetracycline dihydrate	Premix (for feed)	Lobsters	Gaffkemia
Oxytetracycline dihydrate	Premix (for feed)	Salmonids	Ulcer diseases
Oxytetracycline dihydrate	Premix (for feed)	Salmonids and catfish	Bacterial hemorrhagic septicemia and *Pseudomonas* disease
Oxytetracycline hydrochloride	Water treatment	Finfish	Skeletal marking
Sulfadimethoxine ormetoprim	Premix (for feed)	Catfish Salmonids	Enteric septicemia of catfish Furunculosis
Sulfamerazine	Premix (for feed)	Trout	Furunculosis
Tricaine methanesulfonate	Water treatment	Fish	Temporary immobilization

[a] Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

out in the guide, it is unlikely that any action will be taken against them. In effect, this guide allows veterinarians to recommend approved medicated feeds to be fed to minor food-producing animals in an extralabel manner. For example, pheasants can be fed medicated feed that is labeled for chickens or turkeys. The CPG was revised in late 2016 to accommodate the change of medicated feeds containing antimicrobials important in human medicine from over-the-counter (OTC) to veterinary feed directive (VFD) marketing status. It provides a way for veterinarians to order such feeds even though VFDs do not permit legal extralabel use. The CPG is not the answer to the issue of drug availability, but is a temporary solution that should someday be made unnecessary by drug approvals. The CPG is available on the FDA website.

Minor Use and Minor Species Animal Health Act

In 2004, the Minor Use and Minor Species (MUMS) Animal Health Act was passed giving the FDA the

Table 51.5 Veterinary pharmaceuticals approved by the Food and Drug Administration as of May, 2014 for use in miscellaneous minor food-producing animals

Drug	Formulation	Species	Indication[a]
Lasalocid	Premix (for feed)	Rabbits	Coccidiosis
Lincomycin hydrochloride	Water soluble powder	Honey bees	American foulbrood
Oxytetracycline	Premix (for feed) Water soluble powder	Honey bees	American and European foulbrood
Sulfaquinoxaline	Premix (for feed)	Rabbits	Coccidiosis
Tricaine methanesulfonate	Water Treatment	Amphibians	Temporary immobilization
Tylosin tartrate	Water soluble powder	Honey bees	American foulbrood

[a] Listed indications are broad. For specific indications, the drug label or Code of Federal Regulations should be consulted.

opportunity to encourage the approval of drugs for minor animal species and for minor uses in major animal species. Among the provisions of the Act, the MUMS legislation modified the Federal Food, Drug and Cosmetic Act in three significant ways, by providing the options of conditional approval, indexing, and designation for veterinary drugs used in minor animal species (Public Law 108–282).

Conditional Approval

The MUMS Act provides an opportunity for drugs to be conditionally approved. This option is limited to drugs that will be used for minor uses in major species and for minor species, including minor food-producing animals. Conditional approval allows drug sponsors to market the product on a yearly renewal basis for up to 5 years while gathering effectiveness data. All other requirements for a conditional approval (e.g., human food safety) are the same as for a full approval. The standard for conditional approval is “a reasonable expectation of effectiveness” rather than “substantial evidence.” Within the 5 years allowed for conditional approval, the sponsor must provide effectiveness data to the full approval standard. Conditionally approved new animal drugs must be so labeled and are not eligible for extralabel use.

Indexing

The intent of the Legally Marketed Unapproved New Animal Drug Index is to provide a means for sponsors to make products available for markets that cannot meet requirements of the NADA due to small populations, intrinsic value of the animals, wide variety of species, etc. It is limited to minor species, not minor uses. Indexing does not apply to minor food-producing animals as it is reserved for drugs to treat diseases or conditions in animals where human food safety is not a concern. The index is intended to serve the needs of laboratory animals, zoological animals, companion birds, ornamental fish, etc.

Designation

The designation portion of the MUMS legislation created a program for veterinary medicine that largely mirrors what has been done with the orphan drug program in human medicine. Designation is intended to provide incentives to encourage pharmaceutical companies to support drug development for minor species and minor uses. Designated drugs are granted 7 years of exclusive marketing rights beginning on the date of approval or conditional approval. The MUMS Act also authorizes availability of grants to support safety and effectiveness testing of designated new animal drugs.

Programs Supporting the Use of Veterinary Pharmaceuticals in Minor Food-Producing Animals

Minor Use Animal Drug Program

As already noted, the small market size for therapeutic veterinary products for minor food-producing animals makes the time and expense of drug approval unattractive to pharmaceutical companies. To assist and increase drug availability for minor food-producing animals, the United States Department of Agriculture (USDA) sponsors a program to generate data to support such drug approvals.

The Minor Use Animal Drug Program, formerly known as the National Research Support Project #7 (NRSP-7), is a USDA program to support research into the safety and effectiveness of drugs for use in minor species and for minor uses in major species of agricultural importance. This encompasses animals used to produce food or fiber. This program is intended to help fill the need for safe and effective drugs for use in minor food-producing animals, such as sheep, goats, rabbits, game birds, bison, deer, honey bees, and aquaculture species. A review of this program has been published by Ringer et al. (1999). The program accepts requests for needed drugs from a wide range of stakeholders, including veterinarians, researchers, producers, and pharmaceutical companies. In most cases the program funds studies to complete data requirements for effectiveness, target animal safety, human food safety, and environmental safety. As these studies are reviewed and accepted by CVM, the data are gathered into a Public Master File, and made available on the FDA website. A pharmaceutical sponsor can use these data in conjunction with its own manufacturing and labeling information to support an NADA for the product. In this way, costs to the pharmaceutical company are drastically reduced.

Since the Minor Use Animal Drug Program has a limited budget, it generally, but not always, selects projects for minor food-producing animals that will be supplemental to existing products already labeled for use in major food-producing animals. The toxicology portion of the human food safety technical section of an NADA is much too expensive for the program to fund an original approval for a minor food-producing animal. If this work was already done by the pharmaceutical sponsor to support a cattle or swine approval, for example, it does not need to be repeated for the minor food-producing animal. Residue depletion and antimicrobial resistance issues, however, still need to be addressed. Effectiveness and target animal safety need to be demonstrated in the minor food-producing animals and the environmental component must be addressed. Again, if an approval for a major food-producing animal already exists, a categorical exclusion from the requirement to provide an environmental assessment is a likely option, unless the new approval is for use in aquaculture.

At any given time, the Minor Use Animal Drug Program is sponsoring three to five active projects. Working in cooperation with universities, producers, veterinarians, and government agencies, the program leverages a small budget into many studies. Since its inception in the early 1980s, the program has been successful in supporting over 29 drug approvals for a wide range of species. Information about the program and its projects can be found at: www.nrsp7.org.

There are also other entities that follow this basic model of providing public data that can be used to support drug approval for minor species, especially for aquaculture. Public entities such as the US Fish and Wildlife Service and the US Geological Survey conduct research in these areas. Their work has been of great value in the development of new products for managed aquatic stocks.

The Food Animal Residue Avoidance and Depletion Program

The Food Animal Residue Avoidance and Depletion Program (FARAD) assists veterinarians in the establishment of scientifically based withdrawal intervals (not withdrawal times) to prevent the occurrence of illegal residues in edible products derived from food-producing animals treated in an extralabel manner (Payne et al., 1999). A *withdrawal time* is a legal requirement established by the FDA/CVM as part of the drug approval process. A *withdrawal interval* is a recommended preslaughter or milk discard time provided by FARAD to veterinarians in support of the AMDUCA requirement for an extended withdrawal interval for extralabel drug use in food animals.

FARAD utilizes a decision tree approach to the problem and uses all available published data (and unpublished confidential data from pharmaceutical firms whenever possible) to guide the establishment of a withdrawal interval. When tissue or milk data are not available, the establishment of withdrawal intervals sometimes relies on blood (and serum or plasma) pharmacokinetic data to help define the final phase elimination of a drug. In such cases where serum or plasma data are used for estimating tissue residue depletion, it is assumed that the final edible tissue elimination phase will be at least as long as that seen in plasma. All possible data are used to help in this estimation, and whenever a recommendation is made, withdrawal estimations are increased to provide a wider margin of safety. In this way, “safety factors” are built in when assumptions must be made to help ensure that the estimated withdrawal interval will be sufficient. In many cases, data do not exist that can be used to make a withdrawal interval estimation, and the practitioner is advised to consider a different drug for treatment.

Methods for Estimating Withdrawal Intervals for Veterinary Pharmaceuticals Administered to Minor Food-Producing Animals in an Extralabel Manner

When drugs are used in an extralabel manner in food animals, veterinarians need to determine withdrawal intervals to prevent the occurrence of illegal drug residues. FARAD uses several methods to establish withdrawal intervals for drugs administered to minor food-producing animals in an extralabel fashion. All of the methods are dependent in some way on pharmacokinetic and tissue residue data from the minor and/or related major food-producing species. Techniques include comparative pharmacokinetics, allometric scaling, species grouping, and extrapolation based on in vitro or molecular data.

Comparative Pharmacokinetics

The pharmacokinetics of a drug specific to minor food-producing animals, including drug absorption, distribution, metabolism, and excretion, are the key processes determining withdrawal intervals for drugs used in an extralabel manner. These processes differ between species for many reasons, including the anatomy and physiology of the gastrointestinal tract, body composition and relative volumes of different tissues, the capacity and efficiency of different metabolic pathways, glomerular filtration, hepatic blood flow, and plasma protein binding (Lin, 1995; Toutain et al., 2010). When the pharmacokinetics of a drug are not completely known for a minor food-producing species, recommendations may need to be made by extrapolation from major food-producing species. When judging whether such extrapolation is feasible, it is important to consider the many factors that could result in differences in these pharmacokinetic processes between species.

One of the challenges of extrapolating withdrawal times from major to minor food-producing species is determining the appropriate target concentration of the marker residue (tolerance) for the minor species. The tolerance, which is the concentration of the marker residue in the target tissues that drives the withdrawal time in a particular species, is determined by the ratio of the marker residue to total drug residue. Although there may not always appear to be species differences in the types of metabolites formed, there may be significant differences in the ratios of these metabolites. For example, the metabolism of fenbendazole differs even among poultry species (Short et al., 1988); and cattle and sheep have been found to differ significantly in their capacity to metabolize xenobiotic substrates (Watkins et al., 1987). Species differences in metabolite ratios may therefore invalidate the practice of targeting a tolerance set for a major food animal species for a minor food animal species. To ensure safe residue concentrations, AMDUCA requires that if a tolerance is not established for the species or matrix in question, any residues will be considered violative. In food-producing animals, this means that the tolerance and consequently the necessary withdrawal interval may differ between major and minor food-producing animals. Juskevich published a review of comparative food animal drug metabolism that provides an excellent overview covering important factors that must be considered when comparing drug metabolism between species (Juskevich, 1987). Short (1994) published a review comparing factors that impact drug metabolism and disposition in sheep and other domestic ruminants to demonstrate whether pharmacokinetic profiles could be predicted for antimicrobials used in these animal species.

Classic Pharmacokinetic Studies

Studies that describe the pharmacokinetics of a drug in a small group of homogenous animals have been the cornerstone in the study of veterinary pharmacology. If such studies are conducted in more than one species, the results can be compared to inform interspecies differences in drug disposition. Thousands of manuscripts have been published on the pharmacokinetics of drugs in food-producing animals. Some of the studies focus on just one species whereas others are more helpful in that they compare the pharmacokinetics of drugs between major and minor food-producing animals (Modric et al., 1998; Craigmill et al., 2000; Lanusse, 2003; Mestorino et al., 2008; Baert and De Backer, 2003; Taggart et al., 2007). Chapter 3 of this text should also be consulted for an introduction to pharmacokinetic principles.

FARAD has been collecting pharmacokinetic data from the published literature since 1982. The FARAD database contains citations that contain pharmacokinetic data on chemical or drug residues for a variety of animal species. The data from numerous food-producing animals have previously been compiled and published as a reference textbook (Craigmill et al., 2006). In comparison to the major food-producing animals, the minor food-producing animals have considerably fewer published pharmacokinetic studies for the various categories of antibiotics, anthelmintics, nonsteroidal antiinflammatories, and exogenous hormones. Using ruminants as an example, Table 51.6 demonstrates the preponderance of pharmacokinetic-based publications in the FARAD database for cattle versus some of the minor food-producing animals. While the focus of the FARAD data collection has been residue avoidance, considerable data are also available on serum/plasma pharmacokinetics of drugs that can be useful for therapeutic purposes as well. Reviews on the relationship of pharmacokinetic studies to drug residues have previously been published (Lees and Toutain, 2011, 2012)

The limitation of these traditional pharmacokinetic studies, which are carried out in a small group of animals specifically selected for homogeneity, is that they do not provide an accurate reflection of the variability of drug disposition in the target population. Tissue residue studies are typically carried out in a similar manner, with a small number of animals serially slaughtered at various times after drug treatment allowing the establishment of the kinetics of residue depletion. It would be cost-prohibitive to conduct the full pharmacokinetic studies in larger numbers of animals needed to better understand population variability. Fortunately, nonlinear mixed effects models for population pharmacokinetics and metaanalyses provides a tool for pooling sparse data available from different sources to describe the variability in the population, and identify factors that contribute to this variability.

Population Pharmacokinetics and MetaAnalysis

One of the limitations of most comparative pharmacokinetic studies that have been done to date is the small number of animals of each species used. In most studies, all of the animals representing a species have been obtained from one supplier and are of one breed or strain. Therefore, the variability in parameters within a species (intraspecific variability) cannot be assessed. Such unknown variability within a species makes it even more difficult to evaluate variability between species (interspecies). Nonlinear mixed effects models can be used to study population pharmacokinetics and help to define this variability, but these methods require substantial amounts of data to give the best results. Fortunately, the method does not require a rich dataset for each animal in the population, and data can be pooled from various different sources, which makes it feasible to collect the needed data.

Martin-Jimenez and Riviere defined population pharmacokinetics as “a study of the basic features of drug disposition in a population, accounting for the influence of diverse pathophysiological factors on pharmacokinetics, and explicitly estimating the magnitude of the interindividual and intraindividual variability” (Martin-Jimenez and Riviere, 1998). An advantage to this technique is that

Table 51.6 Comparison of numbers of Food Animal Residue Avoidance Databank (FARAD) publications with drug concentration versus time dependent data for select food animal species as of July, 2017. Food animal species were considered for both United States of America and international markets.

it allows for assessment of how clinical factors (age, gender, renal and hepatic function, etc.) impact the pharmacokinetic parameter estimate. It can also be conducted using a multicompartment model to predict residue concentrations in specific tissues. This technique has been used to look at the pharmacokinetics of penicillin in the major food animal species cattle and swine (Li et al., 2014). The application of such a methodology would greatly benefit minor food-producing animals because collective sampling might ultimately establish significant baseline data reflecting the pharmacokinetic parameters of a drug in a field or production setting.

The nonlinear mixed effects approach can also be used to conduct metaanalyses, in which data from multiple published studies are carefully combined to gain a better understanding of a drug's pharmacokinetic variability in the larger population. Species can be included in these models as a categorical covariate explaining some of the observed variability. This approach was applied to procaine penicillin G in cattle and swine (Li et al., 2014) and oxytetracycline nonlactating cattle using FARAD data (Craigmill et al., 2004), as well as ampicillin trihydrate in cattle (Gehring et al., 2005) and flunixin in cattle (Wu et al., 2013). Metaanalysis requires careful selection of data according to predetermined standards to ensure data quality, including such factors as analytical methodology and study design. Under optimal conditions, the metaanalysis is conducted using population pharmacokinetic modeling procedures when individual animal pharmacokinetic data from multiple studies and individual animal covariate data (sex, weight, age, health, etc.) are available.

Physiologically Based Pharmacokinetic (PBPK) Modeling

Physiologically based pharmacokinetic (PBPK) modeling is a very effective method for making interspecies comparisons for drugs. Physiologically based pharmacokinetics offers another way to study interspecies relationships, and has been used extensively for predicting human tissue concentrations of toxicants using animal data. PBPK also offers researchers the opportunity to utilize in vitro metabolism data (K_m and V_{max}) to help predict clearance rates of chemicals in multiple species. PBPK modeling uses physiological and biochemical parameters, therefore this method can be mechanistic as well as predictive. Models can be adapted for different species by changing the physiological parameters accordingly. Physiological parameters used in PBPK models may be measured directly or derived from allometric equations. PBPK models have been developed for fish (Law, 1999), avian species including turkeys, chickens, pheasant, and quail (Pollet et al., 1985; Cortright et al., 2009), cattle (Achenbach et al., 1998; Leavens et al., 2014), horses (Trachsel et al., 2004; Knobloch et al., 2006), swine (Buur et al., 2006; Yang et al., 2012, 2013), rabbits (Tsuji et al., 1985), sheep (Craigmill, 2003), goats (Leavens et al., 2012), and bovine intramammary treatments (Whittem et al., 2012). A model for multiple species (cattle and humans) and routes of administration (oral and intramuscular) has also been developed (Lin et al., 2015). PBPK modeling has been used to evaluate oxytetracycline residues in cattle, sheep, and fish and may prove useful for predicting the depletion of drug residues in the tissues of other minor food-producing animals in the future (Achenbach et al., 1998; Law, 1999; Craigmill, 2003).

Allometric Scaling

For decades, veterinary medicine has used allometric scaling to calculate effective doses and dosage regimens for a variety of animals. For a detailed presentation of the use of allometry for interspecies pharmacokinetic parameter scaling, readers are referred to previously published review manuscripts (Huang and Riviere, 2014; Mahmood et al., 2006; Martinez et al., 2006). Riviere and colleagues (1997) gathered pharmacokinetic parameter data for 44 drugs using the Food Animal Residue Avoidance Depletion program and found that 11 of the 44 drugs showed significant allometric relationships of their pharmacokinetic parameters for extrapolation between veterinary species. Nine of these 11 drugs were antibiotics. Some of the drugs that did not demonstrate allometric relationships with respect to their pharmacokinetic parameters were low hepatic excretion drugs. For the other drugs, the results were equivocal. When this work was recently expanded to 85 drugs, it was found that body weight was significantly correlated with total body clearance and volume of distribution in 77% and 88% of the drugs, respectively (Huang et al., 2015). In this latter study, 12 drugs were identified to have at least one outlier species for clearance and 10 drugs for volume of distribution at steady state.

These pharmacokinetic allometric studies can be used to estimate withdrawal intervals using kinetic parameter data for drugs in blood, serum, or plasma. For unmetabolized drugs (e.g., ones that are not highly protein bound in plasma and are not specifically bound by tissue components), one could expect that tissue residue parameters would mirror blood kinetic parameters. Tissue residue elimination would then be dependent on blood flow and the tissue/plasma partition coefficient. Drugs that are highly fat soluble would be removed from fat depots slowly. This slow removal would subsequently be seen as a prolonged elimination phase.

Species Grouping

Some researchers, including some in the Minor Use Animal Drug program, have been working collaboratively to develop approaches to group minor food-producing animals. This is explored by doing studies in an “indicator” species for each group. The primary focus of this effort has been on aquaculture species. This is due to the large number of aquatic species that are in need of approved drugs to treat diseases and parasites that are often caused by the same organism in multiple species. Several possible ways to achieve this goal include grouping of species based on physiology, drug delivery mechanism, target pathogen, culture system, economic importance, and human food safety concerns (Greenlees and Bell, 1998). Sources of variability in the pharmacokinetics of drugs in aquaculture species include interspecific variability, intraspecific variability, habitat variability, temperature, size/age, and sexual maturity (Gingerich et al., 1998). Poikilothermic animals present a greater challenge than homeothermic animals because the environmental temperature has such a great effect on their physiology. Therefore, studies focusing on poikilothermic animals need to consider environmental temperature as a mixed “physiological” and environmental variable. The FDA CVM accepts some species grouping models, mainly for aquaculture, for new animal drug applications. See Guidance for Industry #61 on the FDA website.

Future Directions: In Vitro and Molecular Studies

In vitro and molecular based research might help establish some differences in drug metabolism before going to whole animal models. In vitro methods for exploring comparative metabolism include P450 assays, microsomes, tissue slices, isolated cells, and cell culture. P450 assays have been used to evaluate species differences for major and minor food-producing animals (Dalvi et al., 1987; Nebbia et al., 2001; Machala et al., 2003; Dacasto et al., 2005). Microsomes from food-producing animals have been used to evaluate gender and breed differences (Dacasto et al., 2005). Another study evaluated the biotransformation of cultured hepatocytes from goats, sheep, and cattle using five different test substrates and determined that cultured hepatocytes appeared to be a good in vitro model to study comparative metabolism of veterinary drugs in these animal species (van ’t Klooster et al., 1994). Reviews of P450 metabolism in veterinary species have been published (Fink-Gremmels, 2008; Antonovic and Martinez, 2011).

Genomic and proteomic methods to evaluate interspecies differences in drug metabolizing enzymes might also be useful for minor food-producing animals. Chapter 50 of this textbook introduces the discipline of pharmacogenomics applied to veterinary species. Examination of DNA using Southern blot analysis can be used to determine if genes exist that code for specific drug metabolizing enzymes. Northern blots may be used to find mRNA transcripts of genes that code for drug metabolism enzymes. For minor food-producing animals, this investigation could start by using cDNA probes for a subfamily of P450 enzymes that are extensively involved in drug metabolism, such as the CYP3 family. Hepatic mRNA from a minor food-producing animal of interest could also be evaluated using commercially available P450 cDNA probes. Using this approach, one could establish only that probe hybridization patterns were similar between the minor food-producing animals being considered. If similar hybridization patterns existed, one could hypothesize that those species evaluated might be similar in drug metabolic capability, at least on a qualitative basis. This hypothesis could then be tested using in vitro (including expression vectors and drug substrate assays) or in vivo methods.

Immunoblotting would be another approach to assess similarities or differences between minor food-producing animals. For this approach, antibodies for the specific protein of interest would need to be developed for minor food-producing animals because the commercial probes/antibodies are usually from nonfood-producing animals (e.g., mouse, rat, monkey, human). Therefore, the use of the commercial antibodies in such assays would be limited for interspecies analysis because the metabolic enzymes from different species cannot be assumed identical. In addition, structural homology does not guarantee functional homology. Nevertheless, because there is considerable sequence conservation across species in the cytochrome P450 enzyme superfamily and metabolic enzymes in general, such studies may be quite useful to characterize potential metabolic enzyme capacities of minor food-producing animals.

As the field of proteomics expands and protein sequence methods become quicker, the identification and characterization of drug-metabolizing enzymes for minor food-producing animals will be easier and more economical. Progress in this area is dependent on increased funding for such research, which may result from growing concern over therapeutic drug residues in food-producing animals.

Summary

Improving drug availability for food-producing minor species is proceeding on several fronts. There has been continual growth in the use of available incentive and research programs. It will take time for these to have a more significant effect. With the great variety of diseases and species that this group represents, every possible incentive must be exploited and every research option explored. This will undoubtedly require that funding for the grants and research programs be increased. Veterinarians, researchers, pharmaceutical companies, government agencies, producers, and consumers all have a stake in the success of this work.

Unique Considerations Pertaining to the Use of Drugs in Food Animals

Michael D. Apley

Introduction

Veterinarians often focus on an area of veterinary medicine and become competent in the pharmacology of drugs associated with that area. As either a veterinarian or a clinical pharmacologist working with food animals, there are additional considerations beyond the animal–drug interaction.

When using drugs in food animals, there must be a consideration of the effect of the drug on the entire population of animals within the production environment, and also within the ultimate supply chain for human consumption. Addressing the safety of meat, milk, and eggs produced by modern agriculture not only involves the evaluation of safety of drug residues, but also other effects such as environmental safety, and selection for resistant bacterial pathogens. The safety of drugs in food animals is no longer only closely observed by regulatory and legislative bodies, but now also by food distribution/retail chains as well as their customers, the consumer. At the time of this writing, due to evolving food retailer policies, we are coming into a period where the effects of social media trends and marketing studies may supersede regulatory and legislative pressures as a major driver in determining what drugs are used in food animals.

The use of drugs in animals intended for use as food primarily involves a subset of veterinary drugs focused on prevention, control, and treatment of infection (both bacterial and parasitic), inflammation, analgesia, anesthesia, reproduction, and performance enhancement. Specific characteristics of these drugs are described elsewhere in this book. This chapter summarizes drugs that should be familiar to a veterinarian involved with food animals, and also describes special considerations related to these drugs when used in food animals.

The lists of drugs and drug groups presented in this chapter are US centric. There are other drugs used around the world in food animals, and perhaps other drug groups. These lists are presented as a means of general appreciation of the breadth of drugs widely employed in food animal production along with considerations for use unique to food animal production; representations of approval or lack of approval, availability, or legality in specific countries are neither intended nor implied.

Extralabel Use

The legality of the use of a drug in food animals in an extralabel manner is dependent on the country in which the drug is used. An example of a cross-border difference is the extralabel use (ELDU) of drugs in the feed of food animals in the USA and Canada. Drugs may be used in feed in an extralabel manner in Canada, but this use is prohibited for food animals in the USA (Health Canada, 2015) An exception in the USA is the allowance for ELDU under regulatory discretion of drugs in the feed for minor food animal species, such as sheep and goats (FDA, 2016). This Compliance Policy Guide (CPG) states that enforcement discretion will be exercised provided that certain requirements are met for ELDU in the feed of minor species.

The regulations for ELDU in food animals in the USA were promulgated and finalized in 1996 to codify the Animal Medicinal Drug Use Clarification Act (AMDUCA) of 1994 (FDA, 1996). Under the regulations, ELDU is "limited to treatment modalities when the health of an animal is threatened or suffering or death may result from failure to treat." This precludes ELDU for production purposes; examples are unapproved estrous synchronization protocols, lactation induction protocols, and extralabel use of growth-promoting hormonal implants. Specific ELDU considerations related to some drug classes are discussed below. It is also important that the veterinarian know the list of drugs for which ELDU in food animals is specifically prohibited. As of this writing, the most current list contains the following drugs (FDA, 2015a).

Under the AMDUCA provisions, FDA has the right to prohibit extralabel uses of certain drugs in animals. The following drugs (both human and animal), families of drugs, and substances are prohibited from extralabel uses

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.
© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.
Companion Website: www.wiley.com/go/riviere/pharmacology

in all food-producing animals, including horses intended for human food:

- Chloramphenicol
- Clenbuterol
- Diethylstilbestrol (DES)
- Dimetridazole
- Ipronidazole and other nitroimidazoles
- Furazolidone and nitrofurazone
- Sulfonamide drugs in lactating dairy cattle, except for the approved use of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine
- Fluoroquinolones
- Glycopeptides
- Phenylbutazone in female dairy cattle 20 months of age or older
- Cephalosporins (not including cephapirin) in cattle, swine, chickens, or turkeys:
  - For disease prevention purposes;
  - At unapproved doses, frequencies, durations, or routes of administration; or
  - If the drug is not approved for that species and production class.

The following drugs, or classes of drugs, that are approved for treating or preventing influenza A are prohibited from extralabel uses in chickens, turkeys, and ducks:

- Adamantane
- Neuraminidase inhibitors

The above list can be found at Title 21 of the CFR, Part 530.41. Currently, no approved drugs are prohibited from extralabel uses in companion animals.

The list of prohibited drugs in the country in which a veterinarian is practicing, or to which food products are being exported, should be well understood. In the United States, it is important to understand that a lactating dairy cow and a dairy cow 20 months of age or older are the same animal for regulatory purposes; the fact that a dairy cow greater than 20 months of age is in the dry period does not change her status as a lactating dairy cow.

An area of ELDU that receives special attention in regulations is the preparation of compounded drug products. In the USA, the use of compounded drugs in food animals had been the subject of compliance policy guide (CPG) Section 608.400 in addition to inclusion in the AMDUCA regulations (FDA, 1996). While the AMDUCA regulations remain unchanged, CPG 608.400 was withdrawn May 19, 2015, and a new draft Guidance for Industry (GFI #230) was released related to compounding from bulk substances. Guidance for Industry #230 addresses compounding from bulk substances in food animals only in that this is not allowed (FDA, 2015b). At the time of this writing the FDA/CVM has asked for input on a list of drugs for which compounding from bulk substances may be allowed in companion animals, with the subject of compounding drugs such as antidotes for food animals from bulk substances remaining unaddressed.

Bulk substances are drug forms which are not the subject of a final New Animal Drug Application (NADA) or New Drug Application (NDA) approval. Compounding in the USA is a very contentious issue as some compounding pharmacies and veterinarians are able to make substantial margins on selling unapproved drug compounds. There are potential downfalls of compounded products, whether from bulk substances or approved drugs, of which the prescribing (or selling) veterinarian should be aware. These include sterility and presence of endotoxin for injectable products, purity, potency, toxicity, violative residues, instability of the final compounded product, and potential lack of efficacy due to insufficient bioavailability. Another issue with compounded products specific to food animals is uncertainty as to the withdrawal time to assure that no violative residues enter the food chain. A compounded product should in no way be confused with a generic product; the latter has an approved FDA label and is subject to good manufacturing processes, which are inspected by the FDA.

The issue of compounding of drugs for use in food animals is a good example of regulatory flux, and that veterinarians must be ever vigilant for regulatory changes.

Residues and Withdrawal Times

The foremost additional responsibility of using drugs in food animals is to protect the safety of the food products from the treated animal(s) by assuring that violative residues do not enter the food chain. An overview of the regulatory process related to residues in animal food products may be found in Food and Drug Administration Center for Veterinary Medicine (FDA/CVM) Guidance for Industry (GFI) #3 (FDA, 2006) and in Chapters 55 and 61 of the present text. The classic approach for determining a slaughter withdrawal time in the USA has been to first determine the toxicity of the compound in laboratory animals by establishing a No Observable Effect Level (NOEL). The NOEL is combined with the regulatory average human weight and a safety factor to establish a total Acceptable Daily Intake (ADI) for the drug residues over a human lifetime. A safe concentration in edible tissues is then calculated by estimating daily intake of muscle tissue, liver, kidney, and fat and using the ADI to establish the residue concentration that may be present in each tissue based on intake. In addition, the presence of residues in milk and eggs are considered for appropriate production classes; if the drug is to be used in an animal producing milk or eggs, the ADI must be partitioned between a serving of muscle tissue, liver, kidney, or fat and consumption of milk or eggs, which may also contain the same residue. In the USA, a tolerance addressing a single marker residue is then developed for the target residue organ (and possibly for other tissues, including milk and eggs if appropriate). In other countries a Maximum Residue Level (MRL) is established, which may be for one residue or a group of residues from the drug. Finally, a withdrawal time for label use of the product is established based on evaluating the MRL/tolerance in light of a study determining depletion of the drug from edible tissues in the target species, and applying statistical methods to these data.

Along with the process of establishing a slaughter withdrawal time, the sponsor must develop and validate an assay for detection of marker drug residue(s) in the target residue organ Other countries may have differing requirements for the process of establishing a withdrawal time for food animal drugs.

In the USA, as in some other countries, the extralabel use of drugs in food animals is allowed when used in accordance with the Animal Medicinal Drug Use Clarification Act (AMDUCA) regulations (FDA, 1996). In these cases, the veterinarian is responsible for assuring that no violative residues enter the food chain and is required to assign an exaggerated slaughter withdrawal time. In cases where the drug is approved for use in that species, during the approval process it was required to establish a tolerance, regulatory method to detect residues, and withdrawal time for that approval. Therefore, the veterinarian is often able to minimally extend the withdrawal time if the label regimen is used. If there is no approval in that species, or an altered regimen from that on the label is used, then the veterinarian must find information to support the assignment of an exaggerated slaughter withdrawal time, or else the animal must not enter the food chain. For the USA, and some other countries, the veterinarian has access to the Food Animal Residue Avoidance Databank (FARAD, or gFARAD for the global version) to aid in this process (FARAD, 2015). If information is not able to be found to assure that no violative residues will occur, the treated animal must not enter the food chain.

The lack of a tolerance for a drug used in food animals requires full attention to potential residues. The presence or absence of a tolerance may be evaluated in the USA by accessing 21 CFR part 556 (FDA, 2015c). Other countries or unions may have their own lists, or adopt standards such as Codex Alimentarius (CODEX, 2013). If there is no tolerance for the species in which the drug is being used, then the concentration that can be detected by the most sensitive assay essentially becomes the tolerance, which historically has continued to decline as analytical technology advances. Estimating slaughter withdrawal times by extrapolating beyond available data down to “zero” may be hampered by the fact that drug elimination from edible tissue may be very different at concentrations lower than concentrations observed in available data. This topic is further discussed in Chapter 61.

Another common challenge in avoiding violative residues is the difference in tolerances and/or MRLs between exporting and importing countries. If a food animal product originates in the USA, use of drugs in production settings must take into account whether the food product(s) might be exported to Russia, the European Union, Japan, China, or South Korea, as examples. In some cases the difference may be as extreme as the US tolerance for total residues of tetracyclines (e.g., chlortetracycline, oxytetracycline, and tetracycline) of 2000 ppb compared to no tolerance or an MRL of 10 ppb in an importing country.

There are some specific cases in the USA where a lapse of residue awareness can cause significant regulatory issues for a veterinarian and their client(s). The first example is that gentamicin has an approval in cattle for topical use in the eye for infectious bovine keratoconjunctivitis. However, during the approval process, no systemic concentrations were detected after the label regimen and therefore no tolerance was required in edible tissues. It has been demonstrated that gentamicin has prolonged depletion characteristics in the bovine kidney after extralabel systemic administration, which when combined with the absence of an acceptable concentration at slaughter, sets up a drastically prolonged required ELDU withdrawal time of approximately 18 months in cattle.

Another example is the use of penicillin G in swine. Penicillin G is approved for swine; however, the tolerance for swine currently listed in 21CFR Part 556 is zero. The sensitivity of the Kidney Inhibition Swab (KIS) test (35 ppb) and the follow-up Food Safety and Inspection Service (FSIS) mass spectrometery test (25 ppb) have resulted in an issue with violative residues in sows if a sufficient exaggerated withdrawal time has not been used. A tolerance of 50 ppb (negligible residue) in the uncooked edible tissues of cattle has been established.

Alteration of the injection site while observing the rest of the label regimen may be sufficient to drastically alter the slaughter withdrawal requirements. Ceftiofur crystalline free acid is labeled for administration to cattle in either the middle third of the ear or at the base of the ear. Some veterinarians have advised producers to inject this product subcutaneously in the neck for convenience. However, the altered regimen results in a significantly prolonged residue profile, contributing to increased risk for violative residues in addition to unproven efficacy by this route. This is an example of the attending veterinarian not thinking through all the ramifications of ELDU.

The issue of extralabel use of florfenicol in lactating dairy cattle illustrates that the use class of the treated food animal on the product label may be as important as the species. Examination of the tolerances in 21 CFR part 556 reveals a tolerance of 3700 ppb for florfenicol in the liver of cattle. However, lactating dairy cattle are not included on the label as a use class, resulting in an interpretation of no tolerance for florfenicol in edible tissues of a lactating dairy cow. This results in an extremely prolonged slaughter withdrawal time requirement for extralabel use in a lactating dairy cow as opposed to a beef animal. A lactating dairy cow for regulatory purposes is a dairy cow 20 months of age or older, regardless of lactation status. In addition, there is no tolerance for florfenicol in milk, resulting in a prolonged milk discard time. Florfenicol use in lactating dairy cows was highlighted in the 2012 FDA milk residue study; although only 15 violative residues were found out of 1912 samples (0.78%), 10 of these violative residues were florfenicol (FDA, 2015d). Other antibiotics for which this is an issue in lactating dairy cows include tilmicosin, gamithromycin, and tildipirosin.

Antibiotics

Here the term "antibiotics" is used according to the societal use, to include antimicrobials. The relationship of the terms antibiotic and antimicrobial is sufficiently complicated to have merited entire book chapters (Bennett, 2015). While this may at first seem a case of trivial semantics, the subject is actually quite important for products marketed with claims such as "antibiotic free". For example, would sulfonamides and fluoroquinolones be allowed in an animal-derived product which is promoted as antibiotic free? Yes, according to the most pedantic interpretation of the terms because they are by definition antimicrobials and not antibiotics, but in practical usage, no.

Table 52.1 summarizes US food animal antibiotic approvals with approved routes for swine, beef cattle, nonlactating dairy cattle, goats, sheep, chickens, and turkeys. Table 52.1 is US centric but represents classes of antibiotics approved throughout the world. Appearance in Table 52.1 does not guarantee that the antibiotic is currently marketed in the USA. Examples of antibiotics considered important for veterinary use around the world may be viewed in the World Association for Animal Health (OIE) list of antimicrobials of veterinary importance (OIE, 2017). The US approval list in Table 52.1 and the OIE list are very similar as far as the classes cited, with additional class members in use outside of the USA.

Table 52.1 was constructed by reviewing the on-line database for the US FDA *Green Book* at the website Animal Drugs @ FDA (FDA, 2014). All drugs discussed in this chapter may be evaluated for label information at this website. The New Animal Drug Approval Number (NADA) may then be used to access the FDA/CVM Freedom of Information (FOI) Summary database (FDA, 2015e). The FOI summaries provide information for studies conducted during the approval process, including substantial evidence of efficacy, pharmacokinetic studies, microbiology, target animal safety, user safety and areas of human food safety, including toxicology, residue chemistry, microbial food safety, and the analytical method for residues.

A classification of antibiotic importance to human medicine has been put forth by the FDA/CVM in Appendix A of Guidance for Industry (GFI) #152, and also by the World Health Organization (WHO) (FDA, 2003; WHO, 2011). Antibiotics reported in Table 52.1 are divided by their status as being listed or not listed as medically important for human medicine in the USA. The WHO list of medically important antibiotics would closely resemble the FDA/CVM list, with the addition of some classes such as the pleuromutilins. The WHO also classifies four critically important antibiotic groups as being of highest priority; these are the fluoroquinolones, third and fourth-generation cephalosporins, macrolides, and the glycopeptides. It is important to note that the FDA/CVM and WHO antibiotic classifications are in reference to importance to human medicine, and are not based on the potential for use in food animals to select for resistance in human pathogens.

The routes of administration for medically important antibiotics in Table 52.1 are only listed for their prevention, control, or therapeutic claims. A prevention claim is considered to be when no clinical cases are yet apparent but clinical experience indicates that a disease challenge is imminent. A control situation is when clinical cases have been detected in a population and the antibiotic is administered to both clinically diseased and clinically normal animals in an attempt to stop the further spread of the outbreak. The discussion of these uses has expanded to include discussion of "routine" prevention and control, indicating routine application of these treatment strategies rather than in specific instances based on evaluation of individual animal groups.

More emphasis is being put on the amount of antibiotics being used in food animals. In the USA, the Animal Drug User Fee Act (ADUFA) requires that the FDA/CVM collect and report annual sales of antibiotics with labels that include food animal uses. The relative sales of antibiotics approved for food animals in the USA, as classified by weight of active compound, and reported for the year 2013 are given in Table 52.1. From these data, it is evident that the tetracycline class dominates sales of active compound in food animals in the USA, as opposed to the fluoroquinolones and cephalosporins which comprise a small proportion. An estimate of in-feed use of antibiotics in swine production in the USA based on 2006 data also found that the tetracycline class comprised

Table 52.1 Antibiotics labeled for food animal use in the United States classified by medical importance status with reported sales proportion in 2013, by species and labeled routes of administration. These routes may be as part of a combination product, are approved specific to disease indications, and may also include only specific use classes and age restrictions within the species. This table contains label approvals as represented at *Animal Drugs@FDA*, the electronic version of the *Green Book* containing FDA CVM approvals.

Medically important antimicrobials as defined in Guidance 152 Appendix A

% of antibiotic sales for food animals in USA for this category in 2013	Class	Drug	Swine	Beef cattle, nonlactating dairy cattle	Lactating dairy cattle	Goats	Sheep	Chickens	Turkeys
2.9%	Aminoglycosides	Dihydrostreptomycin			IMM				
		Streptomycin	O	O	IMM			O	
		Gentamicin	W, I, O	T				I	I
		Neomycin	W,M,F,O	W,M,F,O		W,M,F,O	W,M,F,O	W,M,F	W,M,F
		Spectinomycin	O					W, I	I
0.3%	Cephalosporins	Ceftiofur	I	I	I, IMM	I	I	I	I
		Cephapirin			IMM				
0.2%	Fluoroquinolones	Enrofloxacin	I	I	I				
		Danofloxacin		I					
2.6%	Lincosamides	Lincomycin	I,F,W					W,F	
		Pirlimycin			IMM				
6.1%	Macrolides	Tulathromycin	I	I					
		Erythromycin		F,I	IMM			W,F	F
		Gamithromycin		I					
		Tildipirosin		I					
		Tilmicosin	O	O,I					
		Tylosin	F,I,W	F,I				F,W	W
		Tylvalosin	W						
9.0%	Penicillins	Amoxicillin			IMM				
		Ampicillin	O,W,I	O,I	I				
		Cloxacillin			IMM				
		Hetacillin			IMM				
		Penicillin G	I	I	IMM				W

4.2%	Sulfonamides	Sulfadimethoxine		O,W,I	I			W	W
		Sulfadimethoxine/ Ormetoprim						F	F

		Sulfachlorpyridazine	W,O	W,O,I					
		Sulfaethoxypyridazine	W	W,O,I					
		Sulfamerazine						W	W
		Sulfaquinoxaline		W				F,W	F,W
70.8%	Tetracyclines	Chlortetracycline	W,F,O	W,F,O			F	W,F	W,F
		Oxytetracycline	W,I,F	W,I,F,O	I		W,F	W,I,F	W,I,F
		Tetracycline	W	W				W	W
Not Individually Reported = 3.9%	Amphenicols	Florfenicol	W,F	I					
	Streptogramins	Virginiamycin	F	F				F	F
Antimicrobials not categorized as medically important as defined in Guidance 152 Appendix A									
79.3%	Polyether Ionophores	Monensin		F		F			F
		Lasalocid		F			F	F	F
		Laidlomycin		F					
		Salinomycin						F	
		Narasin	F					F	F
20.7%	Aminocoumarins	Novobiocin			IMM				
	Glycolipids	Bambermycins	F					F	F
	Polypeptides	Bacitracin zinc	F	F				F	F
		Bacitracin Methylene Disalicylate	F	F				F	F
	Pleuromutilins	Tiamulin	W,F						
	Quinoxaline derivatives	Carbadox	F						

F, feed; IMM, intramammary; I, injectable; IU, intrauterine; M, milk; O, oral; S, solid dose implant; T, topical; V, intravaginal; W, water.

approximately two-thirds of total use as classified by weight of active compound (Apley et al., 2012).

Antibiotic sales data for 2012 are also available for 26 countries in the European Union, as reported in the European Medicines Agency (EMA) European Surveillance of Veterinary Antimicrobial Consumption (ESVAC) (EMA, 2014). These data are reported in a different manner than for the USA, adjusted with a "population conversion unit," which adjusts the kg of active compound sold in relation to kg weight of animals (either as populations in the country, transported, or slaughtered) at the estimated time of treatment. In this report, horses are included as food animals. Proportion of all sales for the antibiotics listed as the highest priority in human medicine by the WHO (with ranges across EU reporting countries) were 0.2% (0.01% to 1.2%) for third and fourth-generation cephalosporins, 1.7% (0.02% to 11%) for fluoroquinolones, and 8% (0.04% to 17%) for macrolides. Anticoccidials such as the ionophores are not classified as antimicrobials in the European Union, so are not included in these data. The dominant classes reported in the ESVAC report were the tetracyclines (37%), penicillins (22%), sulfonamides (10%), and macrolides (8%). Although caution must be exercised in comparing these data to the US proportions presented in Table 52.1 due to differences in reporting methods, it appears that the dominant classes of antibiotics used in food animals in the EU mirror those used in the USA

There is an important caveat in that sales data are not necessarily an accurate indication of how and where antibiotics are being used in food animals. A study evaluating sales versus actual end-user data in Denmark and the Netherlands confirmed that detailed use data is needed to define how and where antibiotics are being used in food animals (Bondt et al., 2013).

The concerns about antibiotic use in food animals may be collectively addressed with the term "microbial safety". The most meaningful distinction in the consideration of microbial safety is whether or not the class of antibiotics is classified as important to human medicine. The second critical consideration is if nonmedically important antibiotics may coselect for resistance to medically important antibiotics when used in food animal production systems.

Areas of the world have progressed at different rates in evaluating and addressing concerns about resistance in human pathogens related to use of antibiotics in food animals. Prohibition of antibiotics for growth promotion started in Europe with Sweden in 1986. Denmark banned growth promotion use of avoparcin in 1995 and virginiamycin in 1998. The use of all antibiotics for growth promotion in Denmark, except in pigs up to 35 kg live weight, were removed due to a voluntary stop in 1998. The last use of antibiotic growth promoters in Danish pigs up to 35 kg live weight were phased out in the fourth quarter of 1999 (DANMAP, 2010).

The precautionary principle has been used as a guide in addressing antibiotic growth promoters in the EU (EU, 2007) "The precautionary principle enables rapid response in the face of a possible danger to human, animal or plant health, or to protect the environment. In particular, where scientific data do not permit a complete evaluation of the risk, recourse to this principle may, for example, be used to stop distribution or order withdrawal from the market of products likely to be hazardous."(EU, 2011).

Based on this principle, the EU banned the use of avoparcin for growth promotion in 1997, and then in 1999 also banned bacitracin, spiramycin, tylosin, and virginiamycin for this use (Aerestrup et al., 2010). Anticoccidials are not captured in the antimicrobial use estimates in the EU; they are classified as anticoccidial feed additives and their use for this purpose continues to be allowed. The EU removed the final four antibiotics from approval for growth promotion in 2006; these were monensin and salinomycin (ionophores), avilamycin (an oligosaccharide), and flavophospholipol (bambermycins, seen as a glycolipid in Table 52.1). None of these compounds are classified as medically important in the USA; nonmedically important antibiotics such as the ionophores and the bambermycins will continue to be allowed for growth promotion use in the USA after the implementation of GFI #209 in 2016.

In the USA, concerns led to GFI Document #209 (2012) which called for voluntary compliance in removing growth promotion claims from labels of medically important antibiotics and also adding the requirement for veterinary supervision or oversight in the uses of these antibiotics in the feed or water for prevention, control, or therapy of diseases in food animals (FDA, 2012a). All 26 sponsoring companies, representing 283 labels, agreed to comply with GFI 209. The FDA/CVM followed GFI 209, with GFI #213, and fully implemented the recommendations on January 1, 2017. As of that date, all medically important antibiotics added to feed and water will require veterinary oversight and a written order compliant with the Veterinary Feed Directive (VFD). The VFD requirements are discussed in more detail in Chapter 59.

The microbial safety of antibiotics to be used in food animals in the USA is addressed during the approval process through two main components, the first a qualitative risk assessment described in GFI #152. In this process, rankings of high, medium, or low are determined for the release of a resistant organism (*Salmonella* or *E. coli*) in the food animals, the exposure of humans to this resistant organism through products derived from the animals, and then the consequence of this exposure to human health. The consequence is defined as the ranking of importance in GFI #152, Appendix A, where antibiotics medically important to human health are ranked as critically important, highly important, or important. This process has only been in place since approximately 2001, the date of the GFI #152 document; therefore, older antibiotics used in food animals have not undergone this process.

The second component of the microbial safety evaluation is described in GFI #159, also designated as Veterinary International Committee on Harmonization (VICH) GL36(R). The GFI #159 process involves the potential effect of daily intake of the antibiotic on two characteristics of the human intestinal microbiota; these are disruption of the colonization barrier and increase in populations of resistant bacteria in the human colon. An example of an antibiotic approved in the USA where the withdrawal time was based on the microbiological ADI rather than the toxicological ADI is tylvalosin, approved in 2012. The microbiological ADI was 47.7 μg/kg bodyweight per day, while the toxicological ADI was 190 μg/kg bodyweight per day (FDA, 2012b). Even with the lower ADI, analysis of residues indicated that no withdrawal time was necessary, and therefore no edible tissue tolerance was necessary.

Anticoccidials

Members of this class are presented in Table 52.2. Coccidia are a ubiquitous challenge in food animal species, with especially dire consequences if left unaddressed in chickens and turkeys. In fact, every anticoccidial in Table 52.2 is labeled for chickens. Coccidia may also be a significant health challenge for cattle, with two compounds labeled for feed. One of these is also labeled for water (amprolium), and one is also labeled for milk or milk replacer (decoquinate).

Other antimicrobial drugs that may also be used for anticoccidial effect in food animals include some of the sulfonamides (e.g., sulfaquinoxaline, sulfadimethoxine) and the polyether ionophores. In Europe, the ionophores would be included in the anticoccidial group also, rather than as an antimicrobial. This is an issue of semantics, as the ionophores are an antibiotic with anticoccidial properties. The anticoccidials are not thought to select for resistance to human pathogens, either directly or indirectly through coselection. Some food retailers have needlessly excluded the ionophores from use in their supply chains by demanding "antibiotic free" production systems without realizing that this included the ionophores in the United States. This is an example of where an attempt to achieve kudos for a marketing stance has resulted in the needless removal of a valuable animal health tool with no resulting discernible benefit to human health.

Antiinflammatories

Antiinflammatories are important in food animal veterinary practice and the four products primarily used in the United States are summarized in Table 52.2. Flunixin meglumine is the nonsteroidal antiinflammatory drug approved for food animal use in the United States for the control of pyrexia associated with bovine respiratory disease, acute bovine mastitis, and endotoxemia in cattle. In 2017, a new transdermal flunixin formulation was approved in the U.S. for treatment of pain associated with foot rot (infectious pododermatitis). It is also indicated for the control of inflammation in endotoxemia in cattle, and the control of pyrexia associated with swine respiratory disease. While it is commonly used as an adjunct therapy for respiratory disease in cattle, an analysis of available studies as well as the noninferiority study in the flunixin meglumine/florfenicol product label, indicate that benefits of therapy related to clinical outcome (clinical success) of bovine respiratory disease have not been demonstrated (Francoz et al., 2012; FDA, 2009).

Aspirin is also used in food animals and the containers for these drugs may carry indications for food animals. However, the labels on the containers for aspirin products used in food animals should not be confused with approval labels; no aspirin product for food animals in the United States is the subject of a new animal drug application approval (NADA) number granted by the FDA/CVM. Therefore, there is no tolerance for food animals concerning aspirin in the United States, and any amount detected would be violative as a residue. Some of the liquid aspirin products may be compounded from bulk product, which is specifically prohibited in the AMDUCA regulations. One use of aspirin is in liquid formulations through proportioners in water systems for swine, although a publication on serum pharmacokinetics of sodium salicylate after this route of application raises questions of bioavailability that are inconsistent with field reports of efficacy (Patterson et al., 2007). The use of oral boluses in cattle requires the need for frequent administration, at least twice daily, if adequate concentrations for pain relief are to be achieved (Apley, 2008).

Dexamethasone is a very commonly used steroid in food animal practice. Caution must be used in cattle due to their extreme sensitivity to immunosuppression, abortion, and adverse effects on semen quality in bulls. A dose of 0.04 mg/kg in cattle will inhibit neutrophil function for at least 24 hours after the last dose (Roth and Kaeberle, 1985). In pigs, it takes 2 mg/kg to create this effect. Dexamethasone has also been used as an adjunct

Table 52.2 Nonantibiotics labeled for food animal use in the United States by species and labeled routes of administration. These routes may be as part of a combination product, are approved specific to disease indications, and may also include only specific use classes and age restrictions within the species. This table contains label approvals as represented at *Animal Drugs@FDA*, the electronic version of the *Green Book* containing FDA CVM approvals.

Use classification	Class	Drug	Swine	Beef cattle, nonlactating dairy cattle	Lactating dairy cattle	Goats	Sheep	Chickens	Turkeys

therapy for thromboembolic meningoencephalitis and polioencephalomalacia in cattle. However, a review of the very limited clinical data combined with extrapolation of data from laboratory models and other species would indicate that the use of dexamethasone and flunixin meglumine in these applications may be equivocal at best, and may be likely to cause harm (Apley, 2015). Dexamethasone does not have a residue tolerance in the United States because the toxicity profile during the original drug approval did not merit a tolerance being created. Isoflupredone acetate has less adverse effect potential and more mineralocorticoid activity as compared to dexamethasone.

Extralabel use of other nonsteroidal antiinflammatory drugs, such as ketoprofen and meloxicam, have been utilized in food animals in the United States, with meloxicam gaining extensive popularity due to oral dosing potential, cost, and prolonged activity in cattle. Some other countries have multiple other options for these drugs. In the case of the use of both of these drugs, an exaggerated slaughter withdrawal time must be assigned by the attending veterinarian within a valid veterinary–client–patient relationship.

Production Enhancement Drugs

This general classification of drugs, summarized in Table 52.2, is unique to food animals. They are the subject of approved new animal drug applications and may not be used in an extralabel manner for production purposes. An example was where hormone implants were being used in calves intended for veal production even though this use class is not on the label. The FDA/CVM has made it quite clear that this extralabel use causes the animal to be adulterated.

Steroid implants for use in beef cattle are one of the most reliable efficiency increasing tools available to the beef industry; however, they have been the subject of controversy. Unsubstantiated reports have linked them to cases of early puberty in human females, but when one evaluates the added concentrations of hormones in beef from implanted cattle as compared to nonimplanted beef, and considers the amounts of estrogen and testosterone produced even in prepubescent humans, it becomes apparent that any contribution is minuscule. These standards are reflected in the approval requirements for endogenous sex steroid implants that contain estradiol, progesterone, or testosterone as described in Guidance for Industry number three (FDA, 2006). The FDA/CVM has concluded “that no additional physiological effect will occur in individuals chronically ingesting animal tissues that contain an increase of endogenous sex steroids from exogenous sources equal to 1% or less of the amount in micrograms produced by daily synthesis in the segment of the population with the lowest daily production.” For estradiol and progesterone, prepubertal boys provide the baseline benchmark at 6 and 150 μg per day, respectively. For testosterone, prepubertal girls provide the baseline at 32 μg per day. For synthetic sex steroids such as trenbolone, the FDA CVM recommends a series of laboratory animal tests.

Bovine somatotropin is approved in the United States with an indication of increasing production of marketable milk in healthy lactating dairy cows. As a protein, any amount of this drug in bovine milk will not have an effect on human physiology because this intact protein will not be absorbed in an active form from the gut. Any increase in insulin-like growth factor that occurs from ingestion of milk or other high protein and calorie source foods such as milk and eggs is most likely from the nutritive effect on the human body rather than any absorption of IGF from the food. Nevertheless, the use of bovine somatotropin in dairy cattle has become controversial in the United States and some dairy products are sold with the claim that this drug has not been used in their production.

The beta agonists act as repartitioning agents, with increased muscle and decreased fat produced from the nutritive inputs to the food animal. These drugs not only increase the efficiency of protein production in the animal, they also alter the proportions of different muscle groups in the body so that disproportionately more valuable muscle cuts are increased as compared to less valuable portions of the carcass. Zilpaterol has been the subject of controversy in the United States due to reported adverse health events related to cattle in the immediate preslaughter period when the drugs are administered and also at the slaughter plant. The actual cause of these noted events have been controversial, and at the time of this writing zilpaterol has been voluntarily removed from the market by the sponsor and evaluation of a new flexible dose label in the field is pending.

Ractopamine is approved in cattle, swine, and turkeys. Soon after approval, stress-related adverse events associated with ractopamine were noted in pigs being sent to slaughter. Education on the correct use of the drug as well as dose adjustment were used to alleviate these effects, and the drug remains in use in pigs at this time. Other beta agonists, such as clenbuterol, have been used for animal production in other countries, but this use is specifically prohibited in the United States.

The polyether ionophores are listed under antimicrobials in Table 52.1, but also are very commonly used performance-enhancing drugs in cattle. They are technically an antibiotic because they are a compound produced by one organism which inhibits the growth of another. Their mechanism of action is by inhibiting gram-positive bacteria in the rumen of cattle. This increases the proportion of bacteria that produce propionic acid, the most efficient of the volatile fatty acids for the ruminant animal to convert into glucose in the liver. The polyether ionophores also decrease methane production in the rumen, as well as acting as anticoccidials, as discussed in Section Anticoccidials.

Hormones for Reproductive Use

Reproductive management and therapy is a primary focus of food animal veterinarians and the products for reproductive use listed in Table 52.2 are important tools for this focus. Chapter 27 should be consulted for further details. All are injectable compounds except for altrenogest in swine (used for estrous synchronization) and melengestrol acetate (used for estrous suppression) in cattle. Another method of application is intravaginal devices that release progesterone. Estrous synchronization and super ovulation protocols for embryo collection in cattle are also routine uses of these products.

Controversy has arisen over extralabel use of compounds for reproductive purposes because this does not meet the requirement of “the health of an animal is threatened or suffering or death may result from failure to treat” as outlined in the AMDUCA regulations. Examples of these extralabel uses are lactation induction programs in dairy cattle and some estrous synchronization programs in cattle. The need in some reproductive protocols for an injectable estrogen in the absence of an approved compound has also led to the extralabel use of compounded estrogens. There has also been an interesting, but false, concept that injecting reproductive hormones closer to the reproductive tract will improve their efficacy. This has been used as an argument for injection in the hindquarters of the dairy cow rather than administering the drugs in the appropriate site in the neck.

Some of these hormones are used routinely as abortifacients in cattle. These include cloprostenol, fenprostaline, and dinoprost tromethamine. The use of all of these reproductive hormones require not only a clear understanding of the activity of the drug, but also the physiology within which they are applied.

Antiparasitics

The endectocides inhibit both internal and external parasites. The endectocides in Table 52.2 are macrocyclic lactones, consisting of the avermectins and milbemycins. The benzimidazoles are also referred to as the “white dewormers” due to the appearance of the formulation; these oral products act only on internal parasites. Chapters 39, 40, and 41 go into further details for this class of compounds. Some of the antiparasitics, as for the antimicrobials, are running into challenges with resistance in some animal and parasite species combinations. This issue of increasing importance prompted the FDA Center for Veterinary Medicine to host a stakeholder meeting and to publish a commentary on the meeting in 2014 (Kornele et al., 2014).

The primary species for resistance issues in food animals in North America and much of the world are sheep and goats, especially related to the *Haemonchus* species. Incorrect recommendations abound on the Internet for addressing this issue. Some sites suggest monthly deworming of small ruminants to counter the resistance problem, or that all of the products should be given orally (regardless of label route of indication) because that is “where the worms are”. Both of these concepts are incorrect. Others recommend combinations of products to address resistant parasites, which is a short-term solution. The correct approach to addressing resistant parasites in small ruminants is to only deworm when there is an infection that requires it, which means only in animals that are displaying signs of parasitism, to identify and eliminate the heaviest shedders, and to eliminate classic mismanagement such as overgrazing.

Anthelmintic resistance in nematodes of cattle has also been identified as a worldwide problem (Sutherland and Leathwick, 2011). While *Cooperia* species have classically been considered the nematode resistant to the ivermectins in cattle, there is also evidence that ivermectin resistance is being displayed in *Ostertagia ostertagia* and *Haemonchus* species (Gasbarre et al., 2009; Edmonds et al., 2010).

The obligation of the veterinarian to assure that anthelmintics are correctly selected and utilized has never been more important. As for the antibiotics, occasional new groups may arise but we likely have the majority of the antiparasitic compounds that will need to see us through the next decades. Applying principles of stewardship to assure their continued efficacy is critical.

Anesthetics and Analgesics

The biggest challenge with anesthetics and analgesics for food animals in the United States is that there is only one labeled option. Thiamylal sodium is labeled for injectable use in swine and cattle for anesthesia, but availability varies. The only model accepted by the United States FDA for establishing relief of pain in food animals is for foot rot in cattle. Other uses are considered extralabel for controlling pain in food animals.

For local analgesia, lidocaine is often the drug of choice. None of the lidocaine products with applications for food animals on the bottle are actually labeled for food animals. There is a lidocaine labeled for human use. The AMDUCA regulations allow for the extralabel use of this drug in food animals. Lidocaine should be used with caution in small ruminants as overzealous application may result in an overdose. Anesthesia is often accomplished in food animals through the extralabel use of xylazine, ketamine, and/or acepromazine. Butorphenol may be added to the regimen in some species for increased analgesia.

Nonsteroidal antiinflammatory drugs such as aspirin, flunixin meglumine, ketoprofen, and meloxicam are also used in an extralabel manner for pain in food animals and will require an extended slaughter withdrawal time. In order to avoid violative residues. Phenylbutazone displays an extended elimination half-time in cattle, which allows every other day dosing; however, this drug also displays prolonged slaughter residue characteristics and is prohibited from extralabel use in dairy cows 20 months of age or older. Injudicious use of this drug, especially in show animals, can lead to violative residues.

The need for labeled analgesics and anesthetics for food animals in the United States is critical.

Miscellaneous Food Animal Drugs

Other drugs with food animal labels include gastrointestinal therapeutics such as neostigmine for peristalsis initiation and poloxalene for reduction of bubbles in frothy bloat. There are diuretic drugs labeled for cattle, in oral forms of trichloromethiazide, furosemide, and multiple salts of thiazide. Furosemide is also labeled as an injectable for cattle.

Vitamin E, cupric glycinate (copper), and iron dextran or available as injectables. And, finally, corticotropin (ACTH) is available for beef and lactating dairy cattle.

Summary

While not comprehensive, this summary of drugs available for use in food animals highlights the unique complexities of extralabel use, residues and withdrawal times, consideration of human food safety, and the need to understand not only the animal physiology but also the relationship of the animal and disease to the production system and to the food chain.

Pharmacology in Aquatic Animals

Ron A. Miller

Introduction

Antimicrobials have long been used to relieve pain and suffering and control infections in food-producing animals, including fish. The safe and prudent prescription of effective antimicrobials by veterinarians to treat aquatic animals has contributed immensely to the increased food production capacity of worldwide aquaculture. Use of antimicrobials in aquaculture is, however, not without risk. The American Veterinary Medical Association has published educational materials for veterinarians that describe prudent and judicious use guidelines for antimicrobials in aquaculture (AVMA, 2006). Antimicrobial-resistant bacteria, pathogenic to animals and humans, have been found in and near fish and shellfish farms where medicated feed has been administered (Damir et al., 2013; Miranda et al., 2013; Huys et al., 2001; Guardabassi et al., 2000; Sathiyamurthy et al., 1997; Husevag and Lunestad, 1995). In addition, fish have been implicated as potential reservoirs of zoonotic pathogens (Haenen et al., 2013), some of which may carry resistance genes, including extended-spectrum beta-lactamases (Sousa et al., 2011). Cabello (2006) suggests the unrestricted use of antimicrobials in aquaculture in any country has the potential to affect human and animal health on a global scale, and further suggests that this problem should be dealt with through unified local and global preventive strategies.

Three traditional antimicrobials are currently approved by the US Food and Drug Administration (FDA) for use in finfish and lobsters (Table 53.1). Continued use of the same antimicrobial(s) in the fish-rearing environment will likely increase the potential for emergence and selection of antimicrobial-resistant bacteria in the rearing facility and may diminish therapeutic effectiveness. A Canadian report stated there has been a significant reduction in antimicrobial usage in salmon farming since 2005 (Morrison and Saksida, 2013). Citing improvements in production, health management, and livestock selection, the authors noted few vaccines and limited chemotherapeutic options remain a concern.

In this chapter, many factors will be discussed that should be considered as aquatic animal veterinarians decide whether to prescribe the use of an antimicrobial in a finfish (population). The reader should consult earlier chapters in this text on antimicrobial drugs for further drug-specific discussions.

Legal Considerations when Selecting an Antimicrobial for Use in Aquatic Animals

Prior to making a decision to prescribe treatment for a fish or fish population, careful thought should be taken in selecting the most appropriate antimicrobial, dosage, and route of administration. Aquatic animal veterinarians can be faced with difficult decisions on which approved animal antimicrobial to use or whether to recommend an extralabel (ELU) use of an approved animal or human antimicrobial. In 1994, the Animal Medicinal Drug Use Clarification Act (AMDUCA) provided veterinarians in the US greater flexibility by allowing them to prescribe ELUs of certain approved animal and human drugs for animals under certain conditions. In 1996, the FDA published a regulation that established the conditions under which veterinarians may prescribe ELU of certain approved animal and human drugs for animals (Federal Register, 1996). Discussed here are four of the many key points outlined in the ELU regulations.

A Valid Veterinarian–Client–Patient Relationship

AMDUCA allows ELU only on the order of a licensed veterinarian in the context of a valid veterinarian–client–patient relationship (VCPR). A VCPR can only exist if the veterinarian: (i) assumes the responsibility for making medical judgments about the health of the animal(s) and the need for medical treatment (and the client has agreed to follow the veterinarian's instructions); (ii) has sufficient knowledge of the animal(s) to develop a diagnosis of the medical condition; and (iii) is readily available for follow-up in case adverse reactions or treatment

Table 53.1 Antimicrobials approved for use in US aquaculture in poikilothermic food species. Source: US Food and Drug Administration.

Antimicrobial (manufacturer)	Species	Indication	Dosage regimen	Limitations/ Comments
Oxytetracycline dihydrate (Terramycin® 200 For Fish, Phibro Animal Health)	Pacific salmon	Mark skeletal tissue	250 mg/kg/day for 4 days	Salmon <30 g In feed as sole ration 7 day withdrawal time
	Salmonids	Control of ulcer disease (*Hemophilus piscium*), furunculosis (*Aeromonas salmonicida*), bacterial hemorrhagic septicemia (*A. liquefaciens*), and pseudomonas disease	2.5–3.75 g/100 lb/day for 10 days	In mixed ration No temperature restrictions 21-day withdrawal time
	Freshwater-reared salmonids	Control of mortality due to coldwater disease (*Flavobacterium psychrophilum*)	3.75 g/100 lb/day for 10 days	In mixed ration No temperature restrictions 21-day withdrawal time
	All freshwater-reared rainbow trout	Control of mortality due to columnaris disease (*F. columnare*)	3.75 g/100 lb/day for 10 days	In mixed ration No temperature restrictions 21-day withdrawal time
	Catfish	Control of bacterial hemorrhagic septicemia (*A. liquefaciens*) and pseudomonas disease	2.5–3.75 g/100 lb/day for 10 days	In mixed ration Water temperature not below 62°F (16.7°C) 21-day withdrawal time
	Lobster	Control of gaffkemia (*Aerococcus viridans*)	1 g/lb medicated feed for 5 days	In feed as sole ration 30-day withdrawal time
Oxytetracycline HCl (oxytetracycline HCl Soluble Powder-343®, Phoenix Scientific; Pennox 343®, PennField Oil, Terramycin-343® soluble powder, Pfizer; OxyMarine®, Alpharma; and Tetroxy® Aquatic, Cross Vetpharm Group)	Finfish fry and fingerlings	Mark skeletal tissues	200 to 700 mg oxytetracycline HCl (buffered)/L of water for 2 to 6 h	None
Sulfadimethoxine–ormetoprim (Romet-30®, Pharmaq AS)	Salmonids	Control of furunculosis (*A. salmonicida*)	50 mg/kg/day for 5 days	In feed 42-day withdrawal time
	Catfish	Control of enteric septicemia (*Edwardsiella ictaluri*)	50 mg/kg/day for 5 days	In feed 3-day withdrawal time
Florfenicol (Aquaflor®, Intervet)	Catfish	Control of mortality due to enteric septicemia (*E. ictaluri*)	10–15 mg/kg/day for 10 days	VFD antimicrobial 12-day withdrawal time
	Freshwater-reared finfish	Control of mortality due to columnaris disease (*F. columnare*)	10–15 mg/kg/day for 10 days	VFD antimicrobial 12-day withdrawal time
	Freshwater-reared salmonids	Control of mortality due to coldwater disease (*F. psychrophilum*) and furunculosis (*A. salmonicida*)	10–15 mg/kg/day for 10 consecutive days	VFD antimicrobial 15-day withdrawal time
	Freshwater-reared warmwater finfish	Control of mortality due to streptococcal septicemia (*S. iniae*)	10–15 mg/kg/day for 10 consecutive days	VFD antimicrobial 15-day withdrawal time
Sulfamerazine, Zoetis	Rainbow, brook, and brown trout	Control of furunculosis	10 g/100 lb/day for up to 14 days	In feed 21-day withdrawal time **Not currently marketed**

Approval applies only to the specific antimicrobial that is the subject of a new animal drug application (NADA) or abbreviated new animal drug application (ANADA); active ingredients from other sources (e.g., bulk antimicrobial from a chemical company or similar compounds made by companies other than those specified in the NADA) are not approved new animal antimicrobials.

Approval applies only to use of the antimicrobial for the indications and manner specified on the label.

VFD, Veterinary Feed Directive.

failure is encountered. Such a relationship can only exist when the veterinarian has recently seen and is personally acquainted with the care of the animal(s) by virtue of examination and/or by visits to the premises where the animal(s) are kept.

General Conditions for ELU

ELU is limited to situations where an animal's health is threatened or where the animal may suffer or die without treatment. Before a veterinarian can legally prescribe an approved animal or human drug one of these general conditions must also be met: (i) no animal drug is approved for the intended use; (ii) an animal drug is approved for the intended use, but the approved drug does not contain the active ingredient you require; (iii) an animal drug is approved for the intended use, but the approved drug is not in the required dosage form you require; (iv) an animal drug is approved for the intended use, but the approved drug is not in the required concentration; and (v) an animal drug is approved for the intended use, but the veterinarian has found, in the context of a valid VCPR, that the approved drug is clinically ineffective when used as labeled.

In the ornamental fish industry (nonfood-producing), veterinarians can prescribe an approved human drug for an ELU even if an approved animal drug is available if the other conditions of AMDUCA are met. Whether prescribing drugs for food-producing fish or ornamental fish, thorough recordkeeping is critical. Records of drugs used, condition treated, animal species treated, dosage administered, treatment duration, number of animals, and drug withdrawal parameters must be kept for 2 years or as required by federal or state law, whichever is greater. Thorough labeling of the drug dispensed on the veterinarian's order is critical, including the veterinarian's name, the name of the dispensing pharmacy, and directions for the end user similar to that described for recordkeeping.

Conditions for ELU in Food-Producing Animals

Prior to prescription of an approved animal or human drug for an ELU in a food-producing animal, the veterinarian must: (i) make a careful diagnosis and evaluation of the condition to be treated; (ii) have an appropriate medical rationale for using a specific drug; (iii) make sure the client maintains the identity of the treated animal(s) in the record; (iv) establish a substantially extended withdrawal time supported by scientific information, and, if such information is nonexistent, take appropriate measures to assure that the animal(s) and its food products will not enter the human food supply; and (v) ensure that no illegal residues, including antimicrobial residues, occur and that the client follows the established withdrawal time before marketing food products made from treated animals.

Antimicrobials Prohibited from ELU in Animals

Under the AMDUCA provisions, FDA has the right to prohibit ELU of certain drugs in animals. Currently, no approved antimicrobials are prohibited from ELU in companion animals (including aquarium or pet fish). The following drugs (both human and animal), families of drugs, and substances are prohibited for extralabel animal and human uses in food-producing animals:

- Chloramphenicol
- Clenbuterol
- Diethylstilbestrol (DES)
- Dimetridazole
- Ipronidazole and other nitroimidazoles
- Furazolidone and nitrofurazone
- Sulfonamide drugs in lactating dairy cattle (except approved use of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine);
- Fluoroquinolones
- Glycopeptides
- Phenylbutazone in female dairy cattle 20 months of age or older
- Cephalosporins (not including cephapirin) in cattle, swine, chickens, or turkeys:
  - For disease prevention purposes;
  - At unapproved doses, frequencies, durations, or routes of administration; or
  - If the drug is not approved for that species and production class.

The following drugs, or classes of drugs, which are approved for treating or preventing influenza A, are prohibited from ELU in chickens, turkeys, and ducks:

- Adamantanes
- Neuraminidase inhibitors.

Routes of Antimicrobial Administration in Fish

Table 53.2 shows antimicrobial dosages by various routes of administrations that have been reported in the literature (Reimschuessel et al., 2012). Many of these dosages are unapproved in many countries, and were used in many of these studies for the purposes of investigating the antimicrobial's pharmacokinetics (PK). Researchers and clinicians should consult their regulatory authorities for the approved antimicrobials and dosages in their respective countries.

Table 53.2 Antimicrobial dosages used in fish. Source: Reimschuessel 2012. Reproduced with permission of John Wiley & Sons.

Antimicrobial	Dosage	Interval	Route	Comments
Amikacin	5 mg/kg	q12h	IM	
	5 mg/kg	q72h × 3	IM	
Amoxicillin	25 mg/kg	q12h	PO	Rarely used due to few gram-positive pathogens
	40–80 mg/kg	q24h 10 days	PO	
Ampicillin	10 mg/kg	q24h	IM	Sharks
	10 mg/kg	q12h 7–10 days	PO	Sharks
	50–80 mg/kg	q24h 10 days	PO	
Aztreonam	100 mg/kg	q48h 7 days	IM/IP	Used by koi hobbyists
Azithromycin	30 mg/kg	q24h 14 days	PO	
Ceftazidime	22 mg/kg	q72–96h × 3–5	IM/IP	
Cefquinome	5–20 mg/kg	Single dose	IP	Dose used for determining PK
Chloramine-T	20 mg/l	1 h 4 days	Bath	
	2.5–20 mg/l	Flush (various)	Bath	Disinfectant control bacterial gill disease and parasites
	5–10 mg/l	1 h	Bath	
Ciprofloxacin	15 mg/kg	single dose	IM/IV	Dose used for determining PK[a]
Difloxacin	10 mg/kg	single dose	PO	Dose used for determining PK[a]
Dihydrostreptomycin	0.125 mg	single dose	IM/IV	Dose used for determining PK
	10 mg	single dose	PO	Dose used for determining PK
	10 mg/kg	q24h	IM	Sharks
Enrofloxacin	2.5–5.0 mg/l	5 h q24h 5–7 days	Bath	[a]
	30–50 mg/l	4–24h (various)	Bath	
	5–50 mg/kg	q24h × 5–10 days	PO	[a]
	2.5–10 mg/kg	Single dose	IM/IP/IV	Dose used for determining PK
Erythromycin	10–20 mg/kg	Single dose	IP	For BKD before spawning
	50–100 mg/kg	q24h 10–21 days	PO	
	2 mg/l	1 h	Bath	For BKD in eggs
Florfenicol	5–20 mg/kg	q24h 10 days	PO	Salmon
	10–15 mg/kg	q24h 10 days	PO	Dose approved by US FDA for select species
	40–50 mg/kg	q12–24h	PO, IM, IP	Red Pacu
	25–50 mg/kg	Single dose	IM	
Flumequine	10–500 mg/l	1–72 h	BATH	Increase dose in saltwater[a]
	5–50 mg/kg	q24h 5–10 days	PO	[a]
	30 mg/kg	Single dose	IM/IP	IP (and IM) dose levels remain at effective levels for 10 days[a]
	2–25 mg/kg	Single dose	IV	Dose used for determining PK
Fumagillin	30–60 mg/kg	Single dose	PO	Dose used for determining PK
	3–6 mg/kg	Single dose	IV	Dose used for determining PK
Furpyrinol	4–32 mg/L	5 h	Bath	
Gentamicin	3 mg/kg	q72h	IM	Very nephrotoxic to aglomerular fish Bath exposure does not achieve blood levels
	6 mg/kg	Each week	IM	Sharks
Kanamycin	50–100 mg/l	q72h 5 h × 3	BATH	Nephrotoxic some species Change water 50% between treatments
	50 mg/kg	q24h	PO	Nephrotoxic some species
	10–20 mg/kg	q24h	PO	Sharks
	20 mg/kg	q72h × 5	IP	Nephrotoxic some species
Lincomycin	40 mg/kg	q24h	PO	Japan
Marbofloxacin	10 mg/kg	q24h 1–3 days	PO	Dose used for determining PK
Miloxacin	60 mg/kg	q24h 6 days	PO	Japan
Nalidixic acid	13 mg/l	1–4 h	Bath	
	20 mg/kg	q24h	PO, IM, IV	Other doses used for PK studies
Neomycin	66 mg/l	q3 days × 3	Bath	Toxic to nitrifying bacteria in filter
	20 mg/kg	Single dose	PO	Sharks to prevent bloat, poorly absorbed from gut

(*continued*)

Table 53.2 (*Continued*)

Antimicrobial	Dosage	Interval	Route	Comments
Norfloxacin	30–50 mg/kg	q24h 5 days	PO	
Oxolinic acid	25 mg/l	0.25 h q12h × 3	Bath	
	0.15–1.5 mg/l	10 days	Bath	
	50–200 mg/l	1–72 h	Bath	
	10 mg/kg	q24h 10 days	PO	Freshwater species
	25–75 mg/kg	q24h 10 days	PO	Saltwater species
Oxytetracycline	10–50 mg/l	1 h	Bath	For superficial infections
	20–50 mg/l	5–24 h q24h 5–6 days	Bath	Change 50–75% water between treatments
	55–83 mg/kg	q24h 10 days	PO	Dose approved by US FDA for select species
	25–50 mg/kg	q24h 5–7 days	IM/IP	Produces high levels for several days when given IM
	3 mg/kg	q24h	IV	Red pacu
Piromidic acid	10 mg/kg	q24h 5–10 days	PO	Japan
Sarafloxacin	10–30 mg/kg	q24h 10 days	PO	[a]
Sulfadiazine–Trimethoprim	30–50 mg/kg	q24h 7–10 days	PO	
	125 mg/kg		IP	
Sulfadimethoxine–Ormetoprim	50 mg/kg	q24h 5 days	PO	Dose approved by US FDA for select species
Sulfamerazine	220 mg/kg	q24h 14 days	PO	
	200 mg/kg	q24h 10 days	PO	
Sulfamethoxazole–Trimethoprim	20 mg/l	5–12 h q24h 5–7 days	Bath	Change 50–75% water between treatments
	30 mg/kg	q24h 10–14 days	PO	
Tetracycline	80 mg/kg	Single dose	PO	
Thiamphenicol	20 mg/l	1 h	Bath	
	50 mg/kg	q24h 7–10 days	PO	Japan
Vetoquinol	25–40 mg/kg	Single dose	PO	
Virginiamycin	40 mg/kg	q24h 15 days	PO

BKD, bacterial kidney disease.
Data obtained from many authors.

Injections

Injectable treatments using an antimicrobial are typically used in higher-valued fish (i.e., brood stock, some ornamental species, etc.) due to the labor and care involved in minimizing the potentially significant stress to the animal due to sedation and physical handling. This procedure can be a massive undertaking for commercial producers. Despite these challenges, advantages of administering antimicrobials by injection include assuring that all animals receive the desired dose. Oftentimes the route is intramuscular (IM), but can be intraperitoneal, intravascular, or intradorsal (caudal to the dorsal fin). IM injections are usually administered in epaxial muscles, above the lateral line and near the caudal fin. If an aminoglycoside (e.g., gentamicin) is to be used, care should be taken to inject cranial to the dorsal fin to avoid large doses entering the kidney.

Immersion Baths

Immersion or waterborne treatments are most useful when a large number of animals need to be treated, when limited stress to the animal(s) is important, and of course when it is likely that the pathogen will be exposed directly to the medicated solution (e.g., on surface of fish or gills). There are three classical ways of administering an antimicrobial via a waterborne treatment. *Static baths* (and dips) can be used by adding an antimicrobial solution directly to the holding system. *Flush treatments* are most common in flow-through systems where the entire dose is added and then the water flow is returned to slowly dilute the dose. *Constant flow treatments* are comprised of a constant dose injected into the water system from a stock solution.

The disadvantages of waterborne treatments include expense, waste, and potential environmental contamination. Biological filters may also be compromised due to killing the filter bacteria. A rapid rise in ammonia has been seen using therapeutic concentrations of erythromycin in a catfish recirculating system, but chloramphenicol, nifurpirinol, oxytetracycline, and sulfamerazine did not affect the filter function (Treves-Brown, 2000).

It is also important to consider the ability of an antimicrobial to be absorbed from the water. Lipophilic compounds under a molecular weight of 100 will more likely diffuse across the gills. Antimicrobials that are absorbed from the water include chloramines, dihydrostreptomycin, enrofloxacin, erythromycin, flumequine, furpyrinol, kanamycin, oxolinic acid, oxytetracycline, nifurpirinol, sulfadimethoxine, sulfadimidine, sulfamonomethoxine, sulfanilamide, sulfapyridine, sulfisomidine, and trimethoprim. Antimicrobials that are absorbed poorly or not at all include chloramphenicol and gentamicin (Treves-Brown, 2000; Reimschuessel et al., 2005).

Dipping Treatments

These are a shorter and more controlled method of administering bath treatments. The advantages of this type of treatment are reduced waste (thus reduced expense) and less environmental contamination. The disadvantage of this type of approach is the increased stress to the animals through handling. Therefore most dip treatments are done when fish are small or in pet/aquarium cases, but commercial aquaculture producers have used tarpaulins to contain the antimicrobial (Vavarigos, 2003), and more recently “well boats” to more effectively contain treatments (Burka et al., 2012). Localized topical treatment, often under light anesthesia, has been recommended for small external lesions in pet fish (Stoskopf, 1993; Noga, 1996).

Some studies have used either hyperosmotic infiltration (first high osmolarity, >1200 mOsm/l, then lower osmolarity containing the antimicrobial) or ultrasound treatments to try to improve permeability across the gills. Antimicrobial absorption and elimination can be affected by salinity under normal conditions, and the effects of hyperosmotic treatments have not been adequately studied. Certain antimicrobials that bind divalent cations (such as the tetracyclines) may have their bioavailability compromised by the addition of salts. Ultrasound treatments to enhance absorption may be feasible in a small aquarium setting but have not been studied extensively. Both hyperosmotic and ultrasound treatments are fairly stressful. They are mainly used for vaccination rather than antimicrobial treatment (Treves-Brown, 2000; Navot et al., 2004).

Oral

Oral treatments are the most feasible methods for large commercial aquaculture systems because they are the least stressful for the animals; however, sick fish may not eat, resulting in lessened antimicrobial exposure and compromised therapeutic effectiveness. This was shown in a study where the concentration of oxolinic acid was examined in Atlantic salmon (*Salmo salar*) treated during an outbreak of winter ulcer disease (*Moritella viscosa*). Oxolinic acid was detected in plasma and tissues of healthy fish, whereas levels were below the limit of detection in moribund and dead fish (Coyne et al., 2004a). The moribund and dead fish also had no food in their gastrointestinal (GI) tracts. These results indicate that the antimicrobial appears to help actively feeding healthy fish fight off the infection, whereas fish with clinical signs are anorexic and therefore not receiving the antimicrobial. Variable intake can also occur if fish vary in size. Larger fish will probably consume more of the medicated feed than their smaller, less vigorous counterparts. Palatability, especially of the sulfonamide products, can also be a problem (Poe and Wilson, 1989).

Absorption from the intestinal tract may vary from species to species. As mentioned, saltwater fish will drink and, therefore, antimicrobials may bind cations in the water in their intestinal tracts, affecting bioavailability. The formulation of the antimicrobial may either enhance or decrease absorption.

Various methods for administering oral medications include commercial medicated feed, custom surface-coated feeds, custom feeds (e.g., gelatin diets), medicated live feeds (e.g., *Artemia* grown in or fed antimicrobials), injecting food (e.g., small fish used for food) and tube feeding (Noga, 1996; Treves-Brown, 2000). Obviously, some of these techniques are appropriate only for pet/aquarium fish.

Clinical Approaches by Aquatic Animal Specialists

The importance of implementing responsible antimicrobial use guidelines in clinical practice has been advocated by prominent international organizations (AVMA, 2006; World Organization for Animal Health, 2013; FDA, 2014c). A major component to *responsible use* of an antimicrobial in veterinary medicine is the proper identification of the causative agent, employment of standardized antimicrobial susceptibility testing (AST) procedures (when available), and reporting of such results to a veterinarian. The reporting of susceptibility test results is derived from the interpretation of the laboratory susceptibility test data using clinical breakpoints to denote an isolate as being susceptible, intermediate, or resistant. It is ultimately the responsibility of the veterinarian to make a decision on the appropriate antimicrobial to use therapeutically.

In general, it is not uncommon to encounter the following decision process in an aquatic animal disease veterinary diagnostic laboratory: (i) admit sample to laboratory; (ii) identify causative agent based on gross pathology and/or phenotypic procedures; and (iii) prescribe antimicrobial therapy. However, ideally, the following process would be followed: (i) admit sample to laboratory; (ii) identify causative agent; (iii) conduct standardized AST (CLSI, 2006, 2014a); (iv) consult available interpretive criteria (CLSI, 2014a) or published susceptibility data distributions; and (v) prescribe antimicrobial treatment or alternatively consider improved animal husbandry practices.

Rigos and Smith (2013) published a review of the multitude of factors that should be considered when recommending antimicrobial therapy in an aquaculture setting. They outlined challenges including limited in vitro susceptibility testing procedures (CLSI, 2006, 2014a), limited interpretive criteria to inform the proper dosage to be administered to the animal such that it will be effective and minimize the emergence of antimicrobial resistance (CLSI, 2014b), and differences in the PK dependent upon temperature, salinity, and fish species.

Antimicrobial Susceptibility Testing and Interpretive Criteria

When veterinarians decide whether or not to treat fish with an antimicrobial, they should consider the anticipated PK of the antimicrobial agent in the target fish species under the given conditions (i.e., water temperature, salinity, hardness). They should also choose an antimicrobial that is effective against the disease. A well-controlled and standardized antimicrobial susceptibility test is the best means to obtain this information. A critical component of an AST method is its ability to accurately predict a clinical outcome following treatment and/or detect emerging resistance. In other words, does a likely susceptible in vitro AST result automatically mean therapy will be efficacious? Conversely, does a likely resistant in vitro test result mean therapy will not be efficacious? The purpose of an in vitro antimicrobial susceptibility test is not to mimic in vivo conditions, but rather to provide reproducible results that can be used to predict clinical outcome.

Three reproducible AST methods are currently available for use in veterinary medicine. *Agar and broth dilution susceptibility tests* result in a minimal inhibitory concentration (MIC) for a single bacterial isolate and provide the most clinical relevance, where the MIC may be directly related to an achievable tissue or plasma concentration in vivo. *Disk diffusion susceptibility tests* yield diameters of the zone of inhibition which provide no correlation with achievable concentrations in vivo, but are simple and very affordable tests to run. The *E-test* has also gained popularity as a simple nonstandardized diffusion-based susceptibility test resulting in an MIC shown to yield virtually identical results as the more traditional broth microdilution tests (Luber et al., 2003).

Prior to 2001, aquatic animal disease researchers commonly used AST methods and clinical breakpoint values (susceptible, intermediate, and resistant) developed in their own laboratories. Different methods and breakpoint values prevented accurate interlaboratory comparisons and correlation to clinical cases. Currently, there are two Clinical and Laboratory Standards Institute (CLSI, formerly National Committee for Clinical Laboratory Standards, NCCLS) guidelines for disk diffusion and broth microdilution AST of bacteria isolated from aquatic animals (CLSI, 2007, 2014a). These guidelines have provided standardized methods and quality control procedures that have allowed testing of nonfastidious aquaculture pathogens (termed Group 1 organisms) on unsupplemented Mueller–Hinton media, and *Flavobacterium columnare* and *F. psychrophilum* (Group 3 organisms) on diluted Mueller–Hinton media, in such a way that is reproducible and more reliable (Table 53.3). These documents also describe recommended nonstandardized methods for some of the more fastidious pathogens (e.g., halophilic *Vibrio* spp., streptococci, etc.) (Table 53.4).

How does one decide if an isolate is susceptible, resistant, or intermediate based on a single AST result? The data obtained from the test – MIC or zone diameter – must be interpreted based on potential clinical effect. These interpretive criteria or breakpoints are determined by a number of considerations. MIC clinical breakpoint values are determined from three main sources of information (CLSI, 2007a):

1) PK and/or pharmacodynamic (PD) studies of the antimicrobial in the target animal species used to determine the likelihood of achieving a concentration of the antimicrobial at the target site (resulting in a PK/PD cutoff value, μg/ml).
2) Historical clinical outcomes are correlated with MICs of clinical isolates evaluated (resulting in a *clinical cutoff* value, μg/ml).
3) The antimicrobial MIC distribution for the pathogen is examined to develop epidemiologic cutoffs (resulting in an epidemiological cutoff, ECOFF, μg/ml).

Zone diameters from disk diffusion tests can also be used to interpret an isolate's level of susceptibility. Zone diameter clinical breakpoints are determined primarily from large AST data distributions where each isolate's diameter of zone of inhibition is plotted on the x-axis and its MIC is plotted on the y-axis (Miller and Reimschuessel, 2006; Uhland and Higgins, 2006). Regression analysis has often been used to suggest appropriate zone diameter breakpoint values, but is dependent upon a fairly even distribution of organisms at each MIC tested, particularly in the range of the intermediate MIC ± two to three twofold dilutions (Fuchs et al., 2002). With many of

Organism	Medium	Incubation
Group 2: Strictly halophilic Vibrionaceae	CAMHB + NaCl (1%)	22°C (24–28 hours and/or 44–48 hours) or 28°C (24–28 hours and/or 44–48 hours)
Group 4: Streptococci		
Lactococcus spp.	CAMHB + LHB (2.5% to 5% v/v)	22°C (44–48 hours + CO_2 if necessary for growth)
Vagococcus salmoninarum		
Streptococcus spp.	CAMHB + LHB (2.5% to 5% v/v)	28°C (24–28 hours and/or 44–48 hours + CO_2 if necessary for growth)
Carnobacterium maltaromaticum		
Other streptococci		
Group 5: Other fastidious bacteria		
Atypical *Aeromonas salmonicida*	CAMHB	15°C (44–48 hours)
Aliivibrio salmonicida (formerly *Vibrio salmonicida*) and *Moritella viscosa*	Unknown	4°C or 15°C (6 days)
Tenacibaculum maritimum	Diluted MHB (1:7) + inorganic ion supplementation	25°C (44–48 hours)
Francisella spp.	Modified CAMHB with 2% defined growth supplement (Soto et al., 2010) and 0.1% glucose	28°C (24–48 hours)
Renibacterium salmoninarum	KDM-2	15°C (96 hours with agitation)
Mycobacterium spp.	(CLSI, 2011)	(CLSI, 2011)
Nocardia spp.		
Piscirickettsia salmonis	AUSTRAL-SRS (Yañez et al., 2012)	18°C (92–96 hours and/or 116–120 hours)

CAMHB, cation-adjusted Mueller–Hinton broth; KDM-2, kidney disease medium-2; LHB, lysed horse blood, MHB, Mueller–Hinton broth; NaCL, sodium chloride.

the newer antimicrobials (e.g., florfenicol), encountering resistant organisms is uncommon, and the MIC distribution is heavily weighted toward very susceptible MICs, resulting in an unreliable regression line. Researchers have developed statistically based algorithms to calculate MIC ECOFFs (Turnidge et al., 2006; Kronvall, 2010), which can then be used for surveillance and/or setting clinical breakpoints. The *Aeromonas salmonicida*

MIC and zone diameter ECOFFs for gentamicin, erythromycin, florfenicol, sulfadimethoxine–ormetoprim, sulfamethoxazole–trimethoprim, oxytetracycline, and oxolinic acid were established by the CLSI solely based on a visual inspection of the distribution data (Miller and Reimschuessel, 2006; CLSI, 2014b) (Table 53.5). It is anticipated that the *A. salmonicida* ECOFFs and clinical breakpoints will be revisited by the CLSI's Aquaculture Working Group once an internationally harmonized, statistically based method is endorsed by the CLSI.

By definition, a clinical breakpoint is the classification of projected clinical outcome of patient treatment based on the causative microorganism's in vitro response to an antimicrobial relative to the exposure to that agent that is attainable using the labeled dose regimen for the target animal species for that type of infection and infecting organism (CLSI, 2007a). Thus, the bacterial species – and target animal species – specificity of these values should provide the clinician a level of confidence in these values. It is important to note that interpretive criteria apply only if the laboratory has conducted AST according to specific standardized methods.

Currently, the only universally accepted clinical breakpoint values available for any fish pathogen are those provided in CLSI's VET03/VET04 Supplement (CLSI, 2014b). Provided in that supplement are oxytetracycline and oxolinic acid clinical breakpoints for *Aeromonas salmonicida* (Table 53.6). Clearly, there is a need for additional interpretive criteria that will be useful to aquatic animal health specialists. Future metaanalyses of data taken from the massive PK database published by Reimschuessel et al. (2005), along with additional in vitro MIC and zone diameter distributions can be used to help determine clinical breakpoints in aquaculture. Additional PK/PD investigations may also be needed to determine PK/PD index targets (i.e., time above MIC, AUC/MIC, C_{max}/MIC) most appropriate and applicable to fish.

Timing of Treatment

In aquatic animal medicine, veterinarians are placed in a unique position where vastly different effectiveness rates can be expected depending upon the stage of the disease in the target animal/population. Medication of farm-raised fish in situ is typically metaphylactic. Timing of treatment is critical to preventing de novo infections of healthy members of the treated population. Sicker animals will consume medicated feed at a lower rate than healthier animals. Coyne et al. (2004a) showed 85% of moribund farm-raised rainbow trout that were offered oxolinic acid-medicated feed had no detectable plasma antimicrobial levels, whereas 95% of the healthy fish had detectable levels.

Salinity Effects

The salinity of the surrounding water may induce an effect on the elimination rate of antimicrobials in fish (Choo, 1997). Considerably lower oxytetracycline concentrations were measured in the muscle of treated fish held in seawater. The reduced absorption of oxytetracycline in marine environments is likely due to the complexes the molecule forms with cations found in the water and in the feed. Increased rate of glomerular filtration in individuals in the marine environment may also contribute to the lower absorption. Considerations by practitioners of the salinity and hardness of the rearing systems should always be factored when designing treatment schedules.

Temperature Effects

Temperature has been shown in many PK studies in fish to be an important factor that can affect the PK of many antimicrobials used in aquaculture. This temperature effect may be related to an increased gastric emptying rate, resulting in a faster kinetic profile (absorption, elimination) and lower tissue concentrations of some antimicrobials (oxytetracycline) with increasing temperature.

Antimicrobials Used in Aquaculture

Oxytetracycline

Oxytetracycline is a broad-spectrum antimicrobial widely used in aquatic animal medicine, partly due to its lower order of toxicity, ability to readily distribute throughout the body and into tissues (Chambers, 2001), and general attractiveness from a cost perspective. Oxytetracycline and other tetracyclines are primarily bacteriostatic, and inhibit bacterial protein synthesis by preventing the association of aminoacyl-tRNA with the bacterial ribosome.

Terramycin® 200 for Fish (oxytetracycline dihydrate) Phibro Animal Health is approved by the FDA as an oral antimicrobial to treat specific diseases in salmonids, catfish, and lobster (Table 53.1; FDA, 2014a). The FDA-approved doses or dose ranges are consistent with those approved and/or used in other countries. However, curiously, very few studies in finfish have investigated the PK of oxytetracycline during or immediately after a multiday medicated feed dosing regimen using the FDA-approved dose (2.5–3.75 g/100 lb BW/day or 55–83 mg/kg BW/day). Chen et al. (2004) and Coyne et al. (2004b) both offered ad libitum a dose of 3.75 g/100 lb/day for 10 days and captured oxytetracycline systemic concentrations solely during the depletion phase of the concentration–time profile.

Table 53.5 Zone diameter and minimal inhibitory concentration epidemiological cutoff values for *Aeromonas salmonicida*. Testing Conditions

Medium: Mueller–Hinton agar
Inoculum: Growth method or direct colony suspension, equivalent to a 0.5 McFarland standard
Incubation: 22°C ± 2°C; ambient air; 44 to 48 hours

QC Recommendations

(see Tables 6 and 7 in CLSI document VET03 (CLSI, 2006) for acceptable QC ranges)
Escherichia coli ATCC® 25922[a]
Aeromonas salmonicida ATCC® 33658

General Comments

1. These ECVs are applicable only to isolates of *A. salmonicida* tested under quality controlled conditions, as described in CLSI document VET03 (CLSI, 2006) and VET04-A2 (CLSI, 2014a). Before interpreting results for test strains, ensure that QC test results are within the ranges specified in this supplement.
2. ECVs presented here were established **solely based on** visual inspection of MIC and/or zone diameter data associated with an epidemiological database derived from geographically diverse diagnostic laboratory surveys. **However, it is expected that recently developed statistical analyses will be applied to all susceptibility data distributions to be used for establishing ECVs.** ECVs can be used as a measure of the emergence of strains with reduced susceptibility to a given agent. They are not clinical breakpoints, and, thus, proven clinical relevance has not yet been identified or approved by CLSI or any regulatory agency.
3. The isolates used to establish these ECVs were not from fish that were part of a clinical field trial. These ECVs are to be used in the establishment of interpretive criteria, as described in Appendix C of CLSI document VET02.
4. A "wild-type" (WT) cutoff category implies isolates are susceptible to the antimicrobial (no resistance mechanisms). A "non-wild-type" (NWT) cutoff category implies the isolates possess acquired and/or mutational resistance mechanisms.

NOTE: Information in boldface type is considered **new or modified since initial edition of the VET03/VET04-S.**

Antimicrobial Agent	Disk Content	Zone Diameter Cutoff (mm)		MIC Cutoff (μg/ml)		Comments
		WT	NWT	WT	NWT	
AMINOGLYCOSIDES						
Gentamicin	10 μg	≥ 18	≤ 17	–	–	Established based on **visual inspection of** a zone diameter distribution of 106 *A. salmonicida* isolates (Smith et al., 2007)
MACROLIDES						
Erythromycin	15 μg	≥ 14	≤ 13	–	–	Established based on **visual inspection of** a zone diameter distribution of 106 *A. salmonicida* isolates (Smith et al., 2007)

General Comments

1. These breakpoints are applicable only to isolates of *A. salmonicida* tested under quality controlled conditions, as described in this supplement and in CLSI document VET03 (CLSI, 2006) and VET04-A2 (CLSI, 2014a). Before interpreting results for clinical strains or test strains, ensure that QC test results are within the ranges specified in this supplement.
2. **The papers cited as providing relevant clinical correlation data to support these clinical breakpoints all report work performed before the development of the standard susceptibility test protocols in CLSI document VET03 (CLSI, 2006) and in VET04 (CLSI, 2014a). Consequently, these breakpoints should be updated as data are generated. Additionally, the oxytetracycline and oxolinic acid ECVs used in support of these breakpoints (see Table 5 were established solely based on visual inspection. However it is expected that recently developed statistical analyses will be applied to all susceptibility data distributions to be used for establishing ECVs.**
3. **These breakpoints were established from studies of the treatment of Atlantic salmon in fresh water and seawater. Caution should be taken in extrapolation of these breakpoints to treatments other than those under which they were established.**
4. Antimicrobial susceptibility test breakpoints or interpretive categories provide a classification of projected clinical outcome of animal treatment based on the causative microorganism's *in vitro* response to an antimicrobial agent relative to the exposure to that agent, which is attainable using the normal dose regimen for the target animal species for that type of infection and infecting organism. A "susceptible" (S) breakpoint category implies that an infection due to the isolate may be successfully treated with the normal dosage regimen of an antimicrobial agent recommended for that type of infection and infecting species, unless otherwise indicated. An "intermediate" (I) category implies that an infection due to the isolate may be successfully treated in body sites where the drugs are physiologically concentrated; it also indicates a "buffer zone" that should prevent small, uncontrolled, technical factors from causing major discrepancies in interpretations. A "resistant" (R) category implies isolates are not inhibited by the usually achievable concentrations of the agent with normal dosage regimens and/or fall in the range where specific microbial resistance mechanisms are likely, and clinical efficacy has not been reliable in treatment studies.
5. **The normal dose regimen for oxytetracycline was taken to be approximately 75 mg/kg/day for 10 days. For oxolinic acid, it was taken to be approximately 10 mg/kg/day for 10 days.**

Chen et al. reported maximum serum concentrations 0.04 days after the 10-day regimen of 1.25–5.18 µg/ml in nonsalmonid species. Coyne et al. reported mean plasma concentrations 1 day after the 10-day regimen of 0.25 and 0.21 µg/ml in Atlantic salmon (*Salmo salar*) reared in farm and laboratory conditions, respectively.

Miller et al. (2012) investigated the oxytetracycline pharmacokinetic profile in laboratory-held rainbow trout (*Oncorhynchus mykiss*) fed 74.7 mg/kg/day via oral gavage and reported a mean maximum serum concentration of approximately 1 µg/ml (Figure 53.1).

In June 2006, the FDA approved a supplemental new animal drug application (NADA) which changed the Terramycin® 200 For fish oxytetracycline formulation from the monoalkyl (C8-C18) trimethylammonium or q-salt, to the dihydrate salt (FDA, 2014b). A pharmacokinetics study in shrimp compared oxytetracycline-medicated feeds prepared with the q-salt form and the dihydrate form. This study showed the oxytetracycline q-salt form remained in the environment longer than the oxytetracycline dihydrate form (Reed et al., 2006). The authors suggested the q-salt form is probably more detrimental to the environment and fauna than the dihydrate form.

Sulfonamides and Potentiated Sulfonamides

Sulfadimethoxine–ormetoprim (5 : 1 ratio) is approved by the FDA as an oral antimicrobial to treat furunculosis in salmonids and enteric septicemia in catfish (Table 53.1).

Individually, sulfadimethoxine and ormetoprim are active against a wide array of pathogenic microorganisms. However, when administered in combination, they work synergistically and may lower the incidence of antimicrobial resistance (Bullock et al., 1974). Sulfonamides like sulfadimethoxine are p-aminobenzoic acid (PABA) analogs, which competitively inhibit the incorporation of PABA into folic acid. This prevents the synthesis of folic acid and subsequent bacterial growth. Ormetoprim serves as a potentiator of the antifolate effect of sulfonamides by competitive inhibition of dihydrofolate reductase. Together they offer broad-spectrum antimicrobial activity, which is reported to be effective for treating infections in fish caused by *Yersinia ruckeri* (enteric redmouth disease) (Bullock and Snieszko, 1979), *Aeromonas salmonicida* (furunculosis) (Bullock et al., 1974), and *Edwardsiella ictaluri* (enteric septicemia in catfish) (Plumb et al., 1987).

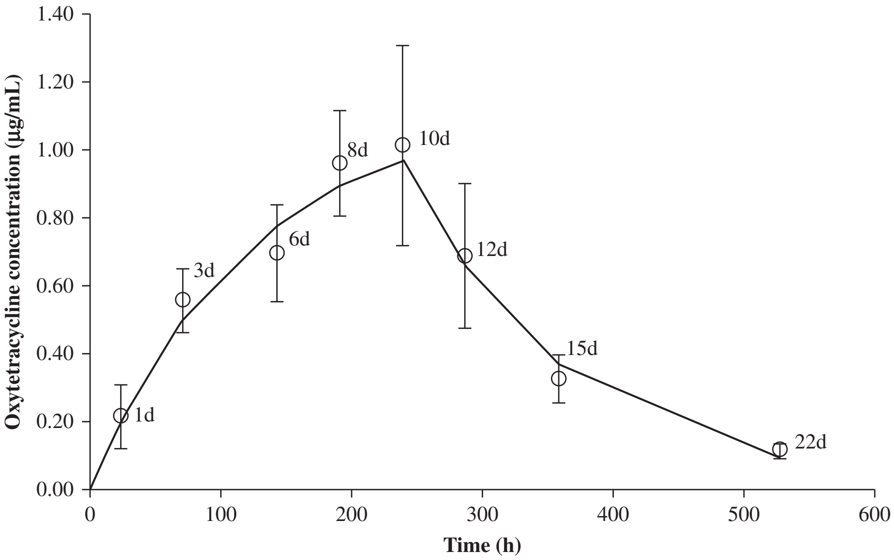

Figure 53.1 Serum oxytetracycline concentrations (mean ± SD; open circles) in rainbow trout after oral administration of medicated feed for 10 consecutive days. The solid line represents the population predicted mean value at each sampling time using a regimen of 75 mg oxytetracycline/kg daily for 10 consecutive days. Source: Miller et al., 2012. Reproduced with permission of Taylor & Francis.

In addition to sulfadimethoxine-ormetoprim, other sulfonamides and potentiated sulfonamides are approved for use in some countries. Sulfamonomethoxine, sulfisozole, and sulfadimethoxine are all approved for use in Japanese aquaculture. Sulfamerazine is approved for use in some countries in Europe. Sulfadiazine–trimethoprim (Tribrissen®) and sulfamonomethoxine–ormetoprim are used in Europe, Canada, and Japan. Romet-30® and these other potentiated sulfonamides have shown potent activity against several fish pathogenic species including *A. salmonicida*, *V. anguillarum*, and *Aliivibrio salmonicida* (formerly *V. salmonicida*) (Samuelsen et al., 1997; Hoie et al., 1992).

Sulfamerazine is approved by the FDA as an oral antimicrobial to treat furunculosis in trout, but is no longer marketed.

Florfenicol

Florfenicol is a broad-spectrum, primarily bacteriostatic antimicrobial with a range of activity similar to that of chloramphenicol. Florfenicol, however, does not carry the risk of inducing human aplastic anemia that is associated with chloramphenicol. The mode of action of florfenicol is by binding to the 50S ribosomal subunit and inhibition of the transpeptidyl-transferase step in protein synthesis, effective against gram-negative and gram-positive bacteria.

Aquaflor® (florfenicol) is approved by the FDA as an oral antimicrobial to control several diseases in catfish and freshwater-reared finfish (Table 53.1).

Florfenicol is also commonly used in Japan, Canada, and Europe to treat furunculosis, columnaris, and other diseases. Cyanphenicol and thiamphenicol are members of the phenicol family and are approved for use in Japan. Despite being banned from use in aquaculture-producing countries in Asia and Southeast Asia, chloramphenicol has been detected in farmed shrimp imported into the European Union. Chloramphenicol is on the FDA's list of prohibited substances for ELU in all food-producing animals due to its link to human aplastic anemia, intestinal problems, and neurological reactions (US FDA, 2017). The European Union (EU) established a minimum required performance limit (MRPL) for this compound of 0.3 µg/kg in tissues from food animals (EU, 2007).

Quinolones

Oxolinic acid is a first-generation synthetic quinolone antimicrobial that possesses potent activity against many bacterial fish pathogens, especially gram-negative organisms. It is accepted for use in aquaculture in Japan and some countries in Europe, being widely used in Norwegian aquaculture (Grave et al., 1999) to treat numerous diseases including furunculosis. Oxolinic acid is administered orally via medicated feed with a recommended dose for finfish of 12 mg/kg BW/day for up to 7 days (EMA, 2005). Samuelsen and Bergh (2004) showed significantly decreased mortality in fish offered oxolinic acid-medicated feed versus the controls after a *Vibrio anguillarum* immersion challenge.

Flumequine similar to oxolinic acid, is a first-generation quinolone active against mainly gram-negative bacteria, and approved for use in Japan and some European countries. Flumequine inhibits DNA-gyrase (Drlica and Zhao, 1997). Vik-Mo et al. (2005) showed efficacy in laboratory trials against an experimental infection caused by *Listonella anguillarum*. Flumequine is also used in shrimp farming to combat vibriosis; however, a recommended dosage has not been determined (FAO/WHO, 2006).

Other quinolone antimicrobials like nalidixic acid and piromidic acid, are approved in Japan, but very little is known regarding the recommended dose, pharmacokinetics, withdrawal times, or extent of their use (Jarboe et al., 1993; Uno et al., 1992; Katae et al., 1979a, 1979b).

Beta-lactams

Amoxicillin is likely the most commonly used beta-lactam antimicrobial in aquaculture worldwide. It is approved for use in Japan and some European countries (Schnick, 2001) to treat furunculosis and other bacterial diseases. The recommended dose is 40–80 mg/kg BW/day for 10 consecutive days (Roberts and Shepherd, 1997). Amoxicillin inhibits cell wall synthesis by preventing peptidoglycan cross-linkage, thus it is primarily active against gram-positive bacteria. In mammalian medicine, amoxicillin is administered with clavulanic acid to decrease its susceptibility to degradation by beta-lactam producing bacteria and to increase the spectrum of action against gram-negative bacteria. However, this has not yet been reported in the aquaculture literature. Amoxicillin is the antimicrobial of choice within the class because it is better absorbed following oral administration than other beta-lactam antimicrobials (i.e., ampicillin) (Prescott, 2006).

Pharmacokinetics of Antimicrobials Commonly Used in Aquaculture in the USA

Oxytetracycline

For many years researchers have investigated the absorption, distribution, metabolism, and elimination profiles of oxytetracycline in various fish and shellfish species (Rigos et al., 2004, 2011; Zhang and Li, 2007; Uno et al., 2006; Reed et al., 2006; Chen et al., 2004; Wang et al., 2004; Coyne et al., 2004b; Bernardy et al., 2003; Haug and Hals, 2000; Abedini et al., 1998; Doi et al., 1998; Du et al., 1997).

Absorption

Tetracyclines are known for their poor absorption from the GI tract, with oxytetracycline categorized as intermediate, meaning when the stomach is empty 60–80% of an oral dose is absorbed. Oxytetracycline absorption in mammals is decreased in the presence of dairy products, calcium, magnesium, and iron or zinc salts in the GI tract. Divalent and trivalent cations bind oxytetracycline decreasing its antimicrobial activity (Lunestad and Samuelsen, 2001). This can be particularly important in aquaculture when oxytetracycline is administered to fish in seawater where cation levels are high (Barnes et al., 1995). Unavoidable contact with seawater occurs when oxytetracycline surface-coated feed pellets are offered. Contact can also occur in the upper GI tract of marine teleost fishes that characteristically drink seawater continuously to compensate for water loss. Encapsulation of oxytetracycline in the feed pellet may avoid direct antimicrobial–cation interaction; however, for absorption to take place the antimicrobial must be in the liquid form, thus mixing with cation-rich fluid in the gut is unavoidable.

Few researchers have reported absorption half-lives ($T_{1/2\alpha}$) of oxytetracycline in fish following nonintravenous routes of administration. Wang et al. (2001) reported a $T_{1/2\alpha}$ of 2.3 hours in orally administered black seabream (*Sparus macrocephalus*).

Bjorklund and Bylund (1990) showed absorption of oxytetracycline in freshwater fish was faster at higher temperatures. At 16°C, the maximum plasma concentration (C_{max}) was reached after only 1 hour (2.1 ± 0.5 μg/ml), while at 10°C and 5°C the C_{max} was reached after 12 hours (5.3 ± 1.7 μg/ml) and 24 hours (3.2 ± 1.8 μg/ml), respectively. Bjorklund and Bylund explained the effect of temperature was due to the fact that fish are poikilothermic, that is their internal temperature varies, often matching the ambient temperature of the immediate environment. Further, an increased ambient and internal temperature should correlate with increased gastric emptying and metabolism in poikilothermic fish species. Therefore, for many farmed fish species in the European Union, the withdrawal times are based on temperature-dependent residue levels and are determined in degree days (Alderman and Smith, 2000). For instance, 150° days for oxytetracycline would represent a withdrawal time of 15 days at 10°C or of 10 days at 15°C.

Distribution

Few studies have investigated the distribution phase of oxytetracycline, with regard to the diffusion of oxytetracycline from the systemic circulation into fish tissues and body spaces (peripheral compartments). Researchers have primarily used the intravenous route of administration in such investigations. Black et al. (1991) calculated a rapid distribution half-life of only 0.9 hours after a single intravenous bolus dose in rainbow trout. Similarly, Rigos et al. (2003) calculated a distribution half-life of only 2 hours in gilthead sea bream. Interestingly, there appears to be little difference in oxytetracycline distribution half-lives in fish and those reported in humans (Gerding et al., 1996). The ability of oxytetracycline to rapidly distribute into the tissues and body spaces where a given pathogen may be targeted, along with its affordability, is part of the justification for its historically widespread use in aquaculture.

Metabolism

Tetracyclines are not metabolized in vivo, but rather are excreted predominantly unchanged in the urine (50–80% of the given dose) (Gerding et al., 1996). Oka et al. (1989) showed that tetracyclines photodecomposed easily in an aqueous solution comparable to a fish pond. Interestingly, Halling-Sorensen et al. (2002) reported other known oxytetracycline degradative products to have antimicrobial activity at levels close to that of their parent compounds. These compounds have largely been ignored in quantitative PK studies due to the minimal metabolism in vivo of tetracyclines, but may need to be considered in future studies.

Elimination

Results of studies on the elimination phase of oxytetracycline from the muscle after oral administration show an obvious decrease in the elimination half-life ($T_{1/2\beta}$) in higher water temperatures. In muscle, $T_{1/2\beta}$ values ranged from 600 hours in brook trout at 7°C (Herman et al., 1969) to 46 hours in perch at 20°C (Wang et al., 2004). Similarly, reported values of $T_{1/2\beta}$ in plasma, serum, and whole blood follow the same temperature-dependent trend as observed in muscle. Haug and Hals (2000) calculated a $T_{1/2\beta}$ of 578 hours in plasma of arctic char held at 6°C in freshwater. Whereas Rigos et al. (2004) calculated a $T_{1/2\beta}$ of 21 hours in plasma of sea bass held at 22°C in saltwater. Poikilothermy is the probable cause of piscine ambient temperature-dependent changes in oxytetracycline elimination. A few inconsistencies in the literature can be found however. Jacobsen (1989) calculated an estimated $T_{1/2\beta}$ of 48 hours from a study conducted in rainbow trout held at 12°C. This value is more than 400 hours less than that observed in another study conducted in rainbow trout held at 11°C (Abedini et al., 1998).

Sulfadimethoxine–ormetoprim

Pharmacokinetic parameters have been determined individually for sulfadimethoxine and ormetoprim in rainbow trout (Droy et al., 1990; Kleinow and Lech, 1992) and channel catfish (Michel et al., 1990; Squibb et al., 1988) using intravenous and oral administration. Pharmacokinetic investigations of the two antimicrobials (Romet®) administered orally together have been conducted in hybrid striped bass (Bakal et al., 2004), Atlantic salmon (Samuelsen et al., 1995), channel catfish (Milner et al., 1994), chinook salmon (Walisser et al., 1990), and rainbow trout (Droy et al., 1989). As with many different pharmacokinetic assessments in fish species, researchers have used several different water temperatures making direct comparisons of data problematic. Temperature-related differences have significant impacts on absorption and excretion kinetics even within the same species (Borgan et al., 1981).

Absorption

Bakal et al. (2004) provided the most complete investigation into the absorption of sulfadimethoxine and ormetoprim when administered in combination. After intraperitoneal (IP) injection in hybrid striped bass at a ratio of 5 : 1, sulfadimethoxine to ormetoprim, the $T_{1/2\alpha}$ was 5.4 hours and 0.7 hours respectively. After oral administration the $T_{1/2\alpha}$ was 3.9 hours and 0.2 hours, respectively. The slower absorption rate after IP administration compared to oral administration may be attributable to the increased surface area enhanced by the peristaltic movements of the GI tract. Also sulfadimethoxine is more soluble in an acidic environment, which could allow for more rapid uptake of the antimicrobial from the stomach. Bakal et al. also calculated a low bioavailability (4.6%) for sulfadimethoxine, indicating poor absorption from the GI tract of hybrid striped bass. Although the 5 : 1 ratio of sulfadimethoxine-ormetoprim is commonly used in feed formulations, Bakal et al. found it does not represent the actual antimicrobial ratio found in the plasma or serum of animals.

Due to the differing absorption rates described here, this antimicrobial combination does not exist in a constant ratio within the animal. To complicate the issue even further, in vitro susceptibility determinations are typically conducted using a ratio of 20 : 1 (Miller et al., 2005), which has been proven to be the optimal ratio of synergism of sulfonamides and their potentiators (Mandell and Sande, 1990).

Bakal et al. (2004) proposed using the total amount of the antimicrobial actually absorbed (area under the concentration–time curve, AUC) in the ratio calculation. This allowed the more close approximation of the average ratio of the antimicrobials in the animal. After oral administration in the hybrid striped bass, Bakal et al. calculated a ratio of 2.14 : 1 (sulfadimethoxine : ormetoprim) based on the AUC for each compound. The relationship of these in vivo-derived ratios to the ratios used in in vitro susceptibility testing is still unclear. How in vivo-derived ratios may be used to help predict therapeutic efficacy for a pathogen with a different MIC ratio also remains to be seen.

Samuelsen et al. (1995) aimed to investigate the bioavailability and pharmacokinetics of sulfadimethoxine and ormetoprim in combination in Atlantic salmon held in 10°C seawater. They showed a considerably higher bioavailability of 39% for sulfadimethoxine and 89% for ormetoprim. Compared to the 4.6% calculated by Bakal et al. (2004) in hybrid striped bass held in 16–17°C freshwater, this exhibits the inconsistency of data present in the literature.

Distribution

Several researchers have investigated the distribution into tissues of sulfadimethoxine and ormetoprim when administered alone in aquatic animal species. Kleinow and Lech (1988) and Squibb et al. (1988) reported comprehensive pharmacokinetics, low protein binding, and wide distribution of radiolabeled sulfadimethoxine following oral and intravenous administration in rainbow trout and channel catfish, respectively. However, only Samuelsen et al. (1995) monitored rainbow trout tissues for the presence of the two compounds after simultaneous administration. They found the sulfadimethoxine and ormetoprim volumes of distribution at steady state to be 0.39 and 2.48 l/kg, respectively. This suggests a much wider distribution of ormetoprim into the tissues outside the plasma than what was seen with sulfadimethoxine. The distribution volume for sulfadimethoxine was similar to that reported previously in experiments involving the single compound: 0.422 l/kg (Kleinow and Lech, 1988), 0.622 l/kg (Squibb et al., 1988), and 0.40 l/kg (Michel et al., 1990). Considerably higher distribution volumes have been reported by researchers for ormetoprim, 4.854 l/kg in rainbow trout (Droy et al., 1990) and 5.503 l/kg in catfish (Plakas et al., 1990). Samuelsen et al. (1995) also noted the kidney had the highest ormetoprim concentration of any organ tested. In salmonids, the kidney contains cells rich in melanin (melanomacrophages). They postulated ormetoprim may bind to the melanin in these cells and could explain the high concentration and prolonged $T_{1/2\beta}$ of ormetoprim in kidney compared to the other organs.

Metabolism

Uno (1993) showed both sulfadimethoxine and sulfamonomethoxine were metabolized by rainbow trout to the N_4-acetylated conjugate, which was the major metabolite, and the N_1-glucuronide conjugate and N_4-acetyl-N_1-glucuronide double conjugate, which were present in lesser amounts. Kleinow et al. (1992) monitored sulfadimethoxine and N_4-acetylated sulfadimethoxine in several tissues and plasma of rainbow trout. They found 20 hours after administration the majority of compound in the plasma was the parent sulfadimethoxine. Conversely, N_4-acetylated sulfadimethoxine predominated in the bile. Slightly higher levels of N_4-acetylated sulfadimethoxine were found in the liver. These findings agree with Squibb et al. (1988) who reported that approximately 90% of the biliary sulfadimethoxine occurred as N_4-acetylated sulfadimethoxine in catfish. These findings also support the view that liver enzymes are instrumental in the extraction of the N_4-acetylated sulfadimethoxine compound from the parent sulfadimethoxine. Plakas et al. (1990) found several unidentified ormetoprim metabolites in the urine of catfish.

Elimination

Samuelsen et al. (1995) showed a fairly rapid elimination for both sulfadimethoxine and ormetoprim, as the elimination half-life, $T_{1/2\beta}$, was 9.9 and 25.6 hours, respectively. In channel catfish $T_{1/2\beta}$ for sulfadimethoxine and ormetoprim was found to be 12.6 and 12.8 hours (Michel et al., 1990; Squibb et al., 1988), whereas Droy et al. (1989, 1990) calculated $T_{1/2\beta}$ for sulfadimethoxine and ormetoprim in rainbow trout to be 16.1 and 17.5 hours, respectively.

Florfenicol

Florfenicol is a relatively new antimicrobial agent to aquaculture, when compared to oxytetracycline and sulfadimethoxine-ormetoprim, which have been used for decades in aquaculture worldwide. Researchers only began studying the PK of florfenicol in fish in the mid-1990s. PK investigations of florfenicol have been conducted in Atlantic salmon (Horsberg et al., 1994, 1996; Martinsen et al., 1993), cod (Samuelsen et al., 2003a), channel catfish (Wrzesinski et al., 2006), rainbow trout (Pinault et al., 1997), and koi and three-spot gourami (Yanong and Curtis, 2005).

Absorption

Horsberg et al. (1996), Martinsen et al. (1993), and Samuelsen et al. (2003a) showed florfenicol absorption after oral administration to be fast and complete with T_{max} and bioavailability values of 6 hours and 99%, 10.3 hours and 96.5%, and 7 hours and 91%, respectively. After oral administration Yanong and Curtis (2005) estimated a $T_{1/2\alpha}$ in koi and three-spot gourami to be 1.4 and 0.6 hours, respectively. After IM administration they calculated a $T_{1/2\alpha}$ of 3.5 and 0.1 hours, respectively.

Distribution

Virtually identical volumes of distribution at steady state were observed by Horsberg et al. (1996) (1.12 l/kg) and Martinsen et al. (1993) (1.32 l/kg) in Atlantic salmon, and Samuelsen et al. (2003a) (1.1 l/kg) in cod. These values indicate florfenicol distributes throughout the body in both species and suggests tissue concentration may be similar to those found in plasma.

Metabolism

Metabolism studies of florfenicol have identified florfenicol amine as the major metabolite in muscle tissue although florfenicol parent is more predominant in skin (FDA, 2005). Florfenicol amine lacks antimicrobial activity, but serves as the marker residue. From 48 hours after administration and throughout a study by Horsberg et al. (1996), florfenicol amine was found in higher concentrations in Atlantic salmon plasma than florfenicol. Samuelsen et al. (2003a) noted a considerable difference in the $T_{1/2\beta}$ of florfenicol after oral administration in cod (39 hours), when compared to that observed by Horsberg et al. in Atlantic salmon (14.7 hours). A negligible temperature difference was cited as a possible explanation; however, no florfenicol amine was detected in either plasma or tissues of cod. The apparent lack of this metabolic pathway in cod may have contributed to the slower elimination of florfenicol and its amine in cod than in Atlantic salmon. However, such a difference in $T_{1/2\beta}$ has not been shown in previous studies with cod and other antimicrobial agents (Samuelsen et al., 2003a; Elema et al., 1994; Rogstad et al., 1993). Metabolism of florfenicol presumably occurs in the liver but this has not been shown experimentally.

Elimination

With the exception of the longer $T_{1/2\beta}$ of cod, florfenicol elimination is quite rapid compared to most other antimicrobials used in aquaculture. Martinsen et al. (1993) and Horsberg et al. (1996) calculated $T_{1/2\beta}$ in Atlantic salmon to be 12.2 and 14.7 hours, respectively. The rapidity of absorption and subsequent elimination in most species has contributed to the attractiveness of florfenicol in aquaculture.

Zoological Pharmacology

Robert P. Hunter

Introduction

Species differences in drug absorption, distribution, metabolism, and excretion (ADME) for numerous pharmaceutical agents have been well documented for domestic species; however, there is limited information concerning the ADME of drugs in nondomestic species. Lack of approved pharmaceutical agents and/or pharmacokinetic data in the literature for exotic, wildlife, and zoo species is a major issue for veterinarians attempting to treat these animals. Under the Animal Medicinal Drug Use Clarification Act (AMDUCA), practitioners take approved agents (veterinary or human) and extrapolate their use to nonapproved species, often with little scientific basis to support this decision. To further complicate treatment, zoo veterinarians often have to formulate the medication(s) into a meal or treat, hoping that the animal will ingest it. Due to lack of patient compliance, the clinician may have to resort to other means of drug administration. Additionally, due to the value of these animals or their status as threatened or endangered species, the traditional method of trial and error for treatment selection is inappropriate. This results in a mentality where no zoo veterinarian wants to be the first to administer an agent/formulation in an untested species.

The range of animals a zoo veterinarian cares for varies from very small invertebrates (honeybees) to megavertebrates such as elephants and whales. There is currently only one United States approval for the class amphibians, four agents approved for use in invertebrates, and eight to ten compounds for mammalian zoo and wildlife species compared to almost 300 for domestic cattle. Various methods have been used to extrapolate/predict safe and effective dosage regimens. No attempt will be made to turn this chapter into a formulary. Excellent formularies already exist to provide for that need (Antinoff et al., 1999; Carpenter, 2012; Hawk et al., 2008; Kreeger and Arnemo, 2007; Nielsen, 1999). This chapter provides information and guidance on comparative physiology, formulation considerations, and dosage scaling across wide and varied species.

Species Groups

Working with exotic animals, even during routine daily care, can be very dangerous. This is magnified when working around sick or injured animals where the patient is subject to increased stress, pain, and deviations from the usual routine — for example, those associated with treatment and drug administration. If given the opportunity, most animals can inflict injury to humans using almost any body part. They can crush with the body or head; kick with exceptional force; or grasp with their hands, body, tail, or trunk. During medication attempts, the individuals administering the treatment are at great risk because they are close to the animal and often working near the head, teeth, fangs, or hands. Safety precautions must be considered prior to treating any animal.

Invertebrates

The numbers of invertebrate zoos and species within those facilities are increasing rapidly. The main concern when treating these species is that they typically lack the membrane barriers that are foundations for therapeutic choices in domestic mammalian species. This likely makes them more susceptible to serious adverse events from agents that are considered safe in mammals, especially anthelmentics or neuroacting agents.

There are only four agents approved for use in invertebrates (shellfish, shrimp, lobsters, or honeybees): bicyclohexylammonium, formalin, oxytetracycline, and tylosin. All of these species are treated as food animals and residues are of concern. These agents have specific approvals in one or more of these species.

Another consideration is the use of invertebrates as drug delivery devices. This is typically done for insectivores or marine mammals (squid to sperm whales). The book *Eat this Bug*, by Davis (1996) may be useful for assisting veterinarians in selecting appropriate “treat” species to use as drug vehicles. This concept is similar to the use of rodents as dosage forms (“fuzzy” dosage forms) for raptors or reptiles. This concept of using insects as

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

dosage forms is commonly used clinically to increase calcium in the diet of insect-eating reptiles (Donoghue and Langenberg, 1996).

Vertebrates

Reptile and Amphibian

With over 4,000 amphibian species, 3,750 species of lizards, 2,500 species of snakes, 270 species of turtles, and 22 species of crocodilians there is currently only one approved product in the USA for this group. Tricaine methanesulfonate (MS-222) is a Na^+-channel–blocking local anesthetic. It is used for temporary immobilization to aid in handling during weighing, measuring, marking, surgical operations, transport, photography, and research.

Route of administration is especially challenging in these species. For amphibians, oral, topical, and injectable routes are common. Topical baths can be very beneficial since the skin of amphibians has similar properties to mammalian mucosal surfaces. The pH and temperature of the bath must be appropriate for the treated species (Mader et al., 1985; Walker and Whitaker, 2000). This can also allow for group treatment of animals that are on display or for treatment off-exhibit in special treatment tanks. As with all treatments, the animals must be monitored so that they are not harmed or injured in the bath (Walker and Whitaker, 2000).

Routes of drug delivery are similar between reptiles and amphibians. Several studies have been done investigating the pharmacokinetics of various agents in all four groups of reptiles: snakes, turtles, lizards, and crocodilians.

Drug metabolism may be affected by prandial state in the snake and other sporadic feeding reptiles. This mechanism allows for minor metabolic investment of digestion to occur after a period of fasting and energy reserve depletion; thus nutrient metabolism peaks about 1 week after feeding. With variable physiological states, drug metabolism and elimination could be affected by feeding intervals. Thus, the effect of feeding could greatly affect the way orally administered pharmacological agents are absorbed by snakes. When a snake consumes a meal, the small intestinal mucosa will increase in thickness at least three times while total length of the small intestine does not change. Correspondingly, villi length is two times prefeeding length, resulting in an increase in small intestine surface area as a result of feeding. Azithromycin absorption in ball pythons was prolonged, compared to all mammalian species reported, based on relatively large mean absorption time (MAT) and T_{max} values.

Four of the 15 circulating azithromycin metabolites: 3′-desamine-3-ene-azithromycin, descladinose dehydroxy-2-ene-azithromycin, 3′-desamine-3-ene descladinose-azithromycin, and 3′-*N*-nitroso,9a-*N*-desmethylazithromycin are unique to the ball python. As azithromycin metabolism in mammals is mediated by several cytochrome P450 isoforms, it is possible that these systemic metabolites are a result of novel cytochrome P450 isoforms, the unique gastrointestinal physiology of the ball python, or some combination of both. The unique gastrointestinal physiology of the snake does appear to lend itself to increased metabolism of xenobiotics. Due to the long GI transit times of boid snakes of >1 week, this presents the opportunity for a xenobiotic, such as azithromycin, to undergo repeated enterohepatic recirculation during the course of a single drug administration. This provides an effect similar to that produced by sustained-release oral formulations in mammals. The percentage of each plasma metabolite differed for only a few metabolites when comparing intravenous with oral administration results from this study (Hunter et al., 2003b). This phenomenon would be expected to correspondingly prolong tissue concentrations of the parent compound and its metabolites. These factors are also likely to have an impact on bioavailability relative to time of feeding in snakes. This would likely make prediction of oral drug absorption dependent, to some extent, on time after feeding.

Reptiles have a renal portal system. This means that a first-pass effect of renally cleared drugs can take place if the animal is injected in the posterior half of the body. This system is not fully understood, and it may not be as restrictive as once believed. However, until definitive data are available, reptiles should be injected in the anterior portion of the body when agents dependent upon renal clearance are administered.

The rehabilitation of wild reptiles, such as sea turtles, requires the use of a variety of different medications; most have never undergone any pharmacokinetic studies in the target species to establish a basis for a safe and efficacious dose. Many of the commonly used treatments have had few studies (pharmacokinetic or efficacy) in any reptile species. This makes use of these drugs guesswork at best and dangerous at worst. For instance, when antimicrobials are underdosed this may not only lead to ineffective treatment of bacterial infections but may also lead to the development of resistant strains of bacteria. Likewise, overdosing may lead to adverse effects. The low basal metabolic rate of reptiles, in general, may correlate to the overall metabolism and distribution of drugs; this, along with the variation in metabolic rates among reptile species, makes dosage determination from dramatically different reptile species far less than desirable — let alone when extrapolation from mammalians species is done. The extent of plasma protein binding varies between species and is temperature dependent. This is a key point to remember when treating poikilothermic species.

Avian

Avian medicine is a field of rapid growth in veterinary medicine. Greater than 95% of all pharmaceuticals used in clinical practice to treat various avian species are based upon empirical doses and the personal experiences of the attending clinician. This raises issues concerning the health of the animals being treated. Therefore, the pharmacokinetics of pharmaceutical agents used to treat avian species is an area of research that is needed to ensure the safe and proper dosing of these animals. However, there is limited information on the pharmacokinetics of agents used to treat psittacines, anseriforms, galiforms, passerines, softbills, and raptors. As a result of the lack of pharmacokinetic data, dosage regimens are designed using linear extrapolation from doses approved in domestic species, such as poultry (Baert and De Backer, 2003). It is possible that use of linear extrapolation could lead to the development of toxicity or lack of efficacy in the treated animal(s) as a result of inaccurate dosing.

Extrapolation of doses is difficult between mammalian and avian species, both qualitatively and quantitatively. The avian renal cortex is more similar to the reptile cortex than the mammalian cortex. Glomerular filtration is not constant in birds, as it is in mammals, and likely has an impact on the pharmacokinetics of pharmaceuticals in avian species (Frazier et al., 1995). Avian species appear to be more susceptible to the renal ischemia and tissue damage of nonsteroidal antiinflammatory drugs (NSAIDs) than the gastrointestinal side effects (Paul-Murphy and Ludders, 2001). While avian cytochrome P450 activities have been reported, their expression and role in avian drug metabolism is not well documented (Walker, 1998).

All of the approvals in this group are for species used as food animals (poultry and galliforms). While it would seem logical to extrapolate a dose from a chicken to an ostrich, this could be equated to extrapolating a dose in horses to elephants.

The concept of "fuzzy" (use of rodents) dosage forms for raptors has been mentioned previously. While rodents can be viewed in many ways (pets, pests, or research test subjects), to the avian (and reptile) veterinarian they are a drug delivery device. In red-tailed hawks, the extent of oral bioavailability of enrofloxacin between intramuscular and "fuzzy" oral dosing was not different, even though the oral T_{max} was five times the intramuscular route (Harrenstien et al., 2000). The difference in T_{max} appears logical when considering dissolution and gastrointestinal transit in these animals.

Mammalian

Oral absorption has been shown to vary within a species. Within domestic dog breeds (Beagle and mongrel), different gastrointestinal transit times and mouth-to-small-intestine transit times have been reported (Sagara et al., 1995). When one considers the anatomical differences between true monogastrics (canine or feline species), hindgut fermentors (rodents, rabbits, horses, or elephants), foregut fermentors (Colobus monkeys, camelids, and kangaroos), and ruminants (cattle, goats, sheep, or antelope), the potential differences are staggering and support the concept that bioavailability is not scalable across mammalian species (Mahmood, 2000, 2002). The large body sizes of some mammalian species produces problems for treatment and places significant limitations on drug delivery. Aside from the weight of the animal, the size, thickness, and density of various anatomical structures can physically hinder drug administration. These concepts are discussed in Chapter 2 of this text.

Small/Pocket Pets/Rodents

There is a wealth of data in the literature concerning the pharmacokinetics and safety of almost every human drug in rodents, such as mice and rats and often for rabbits as well. While ferrets are a laboratory species, research is narrower in scope, but could still be useful in treating these small mammal species. While the doses may be above that needed for efficacy, safety is well understood. The issue is typically formulating the agent into a dosage form that can be used clinically. With the Internet and various medical literature search tools, such as Medline, PubMed, and Highwire, the busy clinician can find information for treating just about any disease in small mammals.

However, there is no published, peer-reviewed information concerning the pharmacokinetics of drugs used in more exotic small mammals, such as hedgehogs, sugar gliders, and honey bears. Historically, mite infestations (*Chorioptic* sp.) in hedgehogs have been treated with either ivermectin or amitraz (Lightfoot, 2000). This treatment has been shown to be effective, but requires weeks or months of therapy. Fleas and lungworms also infest these animals, and with a broad-spectrum, topical endectocide, such as selamectin, treatment could be carried out easily and rapidly, allowing for treatment of both the mite and flea infestations with a single compound (Figure 54.1).

Farmed/Domestic Species

There are ≤50 compounds approved in the United States for sheep, ≤12 for goats, and none for New World camelids. As producers and veterinarians have taken approved agents for cattle, sheep, or goats and extrapolated their use to exotic domestic species, such as New World camelids, safety and efficacy have been the main issues. There are many different species-related factors, including absorption, elimination, and metabolism, that

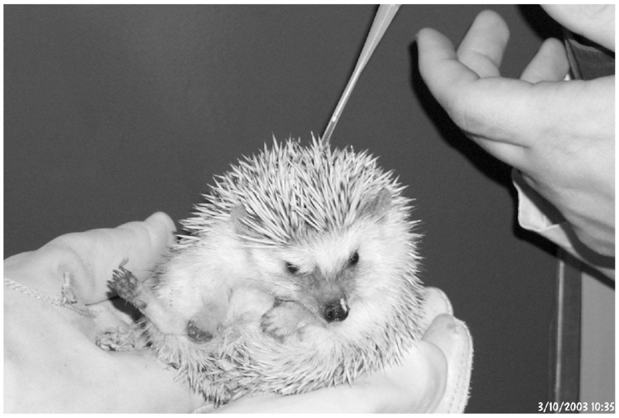

Figure 54.1 Topical dose administration to an African hedgehog.

could lead to variation in the pharmacokinetic parameters between species and possibly decrease the efficacy or increase the toxicity of a compound (Hunter and Isaza, 2002; Short, 1994; Xia et al., 2006). These differences make extrapolation very difficult from one species to another.

An example of species differences in pharmacokinetics is the data for topical doramectin. The mean C_{max} and AUC values for llamas and alpaca was approximately 33% less than that reported for cattle using the same dose and formulation. The mean T_{max} values for both species were 1 day longer than reported in cattle. It appears that the extent of absorption, as evaluated by C_{max} and AUC, is much less than that reported for cattle (Hunter et al., 2004a). This was also the case for moxidectin in these two species (Hunter et al., 2004b).

Zoo/Marine Mammals

All of the routes and issues discussed previously apply to this group of patients. If a well-trained animal can be difficult to treat (which they are), an uncooperative animal can easily prevent almost any unwanted medication from being administered. This is especially true of large carnivores, primates, and megavertabrates (elephants). The animal's combined size, strength, and/or intelligence effectively precludes forcing it to ingest medication or allowing someone to get close enough to manually administer medication.

The capture and chemical immobilization of a variety of zoo and wildlife species has been enhanced with the use of potent synthetic opiates, such as carfentanil (Haigh, 1990). These opiates generally provide rapid induction and relatively long-lasting immobilization. They are usually administered parenterally, the small volumes required making them ideally suited for use in remote delivery systems such as darts (Fowler, 2008). Furthermore, immobilization by these drugs can be completely reversed by the administration of specific opioid antagonists. This is particularly important for immobilization of free-living wildlife, which cannot be closely monitored after the immobilization period. These opioid anesthetic agents have provided zoo veterinarians and wildlife researchers not only a method to restrain animals for a variety of medical and research procedures, but have become an indispensable tool to the practice of zoological veterinary medicine.

Carfentanil has become the drug of choice for a wide variety of nondomestic animal immobilizations, particularly for hoofstock, and has been used either alone or in combination with sedatives for rapid immobilization of captive and free-ranging wildlife. The potency and formulation of this drug allow for a small volume to be administered, which is ideal for remote delivery systems (darts). Naltrexone is the antagonist used routinely in carfentanil immobilization procedures, because it has a longer half-life than other antagonists such as naloxone or nalorphine in domestic species. One adverse effect with the use of carfentanil is that of renarcotization. This is the reoccurrence of the effects of the opioid agonists up to 72 hours after apparent full recovery from the drug. The effect varies in severity from mild sedation to full immobilization and has also been associated with a high incidence of mortality. The choice of antagonist and dose used are important factors in the incidence of renarcotization. Also, certain species appear to have a higher tendency to develop renarcotization than others. Possible mechanisms for renarcotization are listed by Haigh (1990): enterohepatic recycling, metabolism of antagonist to form a metabolite with agonist properties, release of the agonist from body depots after the antagonist has been eliminated, antagonist underdosing, and metabolism of a short-acting antagonist and reestablishment of a longer-acting agonist. Studies are needed to assist with determining the actual cause(s) but there are currently no published PK/PD studies of any opioid agonist or antagonists in exotic ungulates.

Anesthesia of nonhuman primates is risky and stressful. Squeeze cages and darts have been used for administration of parenteral anesthetic agents, and various anesthetics have been administered orally using treat or food items. Although these formulations work well for these primate species, care should be taken to avoid conditioning the animal to associate the treat or personnel with the procedure (Hunter and Isaza, 2002). Transmucosal fentanyl is approved for use in the United States as a preanesthetic agent in humans in a lollipop formulation. When this preparation of fentanyl is chewed and swallowed, it still results in a sedative effect with a corresponding longer T_{max} when compared to true transmucosal absorption. When this formulation was used in a study on great apes (Figures 54.2, 54.3), nine chimpanzees were evaluated with only one being successfully offered a dose

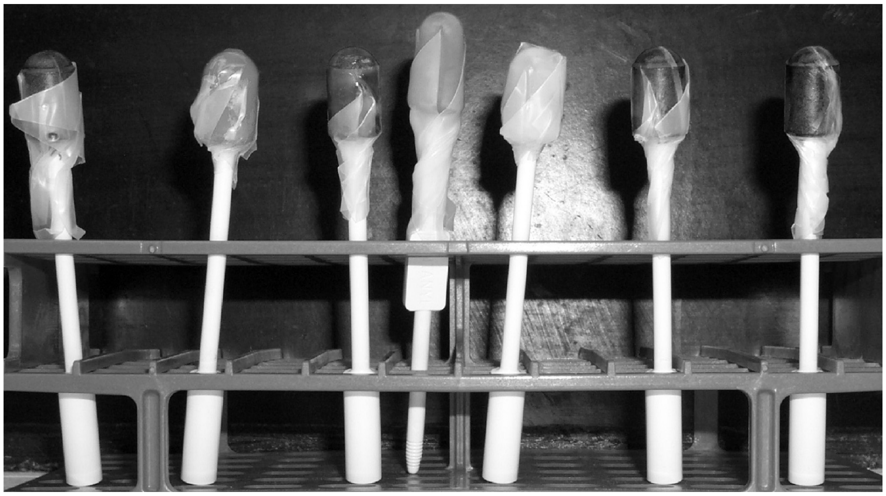

Figure 54.2 The white fentanyl (Actiq®) lollipops were painted with candy coloring to match the colors of the placebo lollipops.

after having refused the lollipop on an earlier attempt; two other animals also refused to ingest their lollipops. All orangutans accepted at least one dose with several accepting two or more. The gorillas accepted multiple lollipops. The orangutans and gorillas demonstrated less stress when darted and showed signs of sedation after fentanyl administration. The main metabolite in humans, norfentanyl, was identified in only one of the test subjects, an orangutan. An effective dosage of fentanyl for orangutans and gorillas was dependent on an effective training program; cooperation of the keeper staff and zoo administration; and facilities that allow for individual, overnight housing of animals. In contrast, chimpanzees were suboptimally sedated with transmucosal fentanyl (Hunter et al., 2004c).

Foot problems affect over 50% of the captive elephant population. These problems may progress to arthritis, a debilitating condition often resulting in euthanasia of the animal. Arthritic elephants are typically treated with a wide variety of antiinflammatory and analgesic drugs, which offer only palliative treatment. Due to the side effects of these agents in domestic species, accurate therapeutic regimens are critical to properly treating diseased elephants. Simply guessing at a dosage can have disastrous consequences, as was illustrated in a case report where lysergic acid diethylamide (LSD) was tested in an

Figure 54.3 Use of fentanyl lollipops to sedate an orangutan.

elephant and the animal died violently within minutes (West et al., 1962).

The lack of pharmacokinetic data is reflected in the sparse number of published studies in elephants. Almost all of these studies have focused on antimicrobials, with little data being reported for analgesic and/or antiinflammatory agents. As a result of the lack of pharmacokinetic data, dosage regimens are designed using the assumption that pharmaceuticals administered to the elephant are absorbed, distributed, metabolized, and excreted in approximately the same manner as horses (Page et al., 1991). However, at least one example exists in the published literature to contradict this statement. For the chiral NSAID ketoprofen, the *S*-enantiomer is cleared from elephant plasma much more rapidly than the *R*-form. This is different than the domestic horse where the *R*-form is cleared more rapidly. This was explained as either selective clearance from plasma in the Asian elephants or as chiral inversion. Also in this study a possible novel metabolite, a Phase II glycine conjugate, was reported (Hunter et al., 2003a).

Allometry in Zoo Medicine

Allometric scaling of pharmaceuticals to predict pharmacokinetics in zoo/exotic animals has considerable benefit for zoological veterinarians. This tool, when used appropriately, can provide an *estimate* for designing dosage regimens. This topic was discussed for minor species in Chapter 51 of this text. The example of differences in ketoprofen inversion across species emphasizes the need to understand and be aware of the assumptions when designing treatment regimens based on allometric scaling data.

Just as mammals can range from a few grams to thousands of kilograms, reptiles and birds can also vary in body weight across a wide range. It has been suggested that it is impossible to derive a single equation correlating body mass to metabolic rate for all 6,000 species of reptiles (Funk, 2000). Without knowledge as to the extent and route of elimination of an administered pharmaceutical agent, extrapolation of dosage regimens from one class to another is difficult, if not impossible, with any certainty. It is apparent that more research is needed on the drug metabolism and excretion capabilities in snakes, let alone reptiles in general. This type of research would increase the ability of clinicians to determine more effective and safe dosage regimens for their patients. Another consideration when using allometry is the nonlinearity of pharmacokinetics in some species (Manire et al., 2003; Rush et al., 2005).

There are two major components of hepatic clearance of xenobiotics: hepatic blood flow and enzymatic metabolism. Renal clearance is the other major route by which drugs are excreted. Renal clearance is composed of three parts: glomerular filtration, active tubular secretion, and tubular reabsorption. Glomerular filtration rate is allometrically scalable in mammalian species, as is *p*-aminohippuric acid clearance (Edwards, 1975; Holt and Rhode, 1976). However, allometric scaling of active tubular secretion and tubular reabsorption have not been reported in the published literature.

The concept of metabolic or allometric scaling has been used as the basis for comparison across species since the 1930s. Benedict's *Vital Energetics* appears to be the first comprehensive discussion on the topic of metabolic scaling. Benedict's work laid the foundation for scaling of metabolic rates across a wide range of species. Metabolic rate for mammals was described by Kleiber (1932, 1961). Various physiological processes such as heart rate, blood volume, and glomerular filtration rates can be predicted reasonably accurately for a wide variety of species based solely on the weight of the animal.

Linear extrapolation is the use of a single mg/kg dose across all species, so that the total amount of drug increases in a linear fashion as body weight increases. When dosages are extrapolated to other species of different weights, this method assumes that dosage versus weight is directly (linearly) proportional. This method assumes that differences in weight and in species pharmacokinetics are not clinically relevant. Although this is the simplest and most common method of extrapolation, it may overdose large animals and underdose small animals.

Metabolic scaling uses the ratio of a known physiological process (i.e., metabolic rate) of two species to estimate a dosage in a species where there are no measured pharmacokinetic data. This method uses the dosage in a specific species and links the dosage to a physiological function instead of the animal's body weight (Dorrestein, 2000; Mortenson, 2001; Sedgwick, 1993; Sedgwick and Borkowski, 1996). In this method the chosen function forces an allometric (log–log) relationship, usually with an exponent of 0.6–0.8. The key assumption is that since most physiological functions follow allometric equations relative to body weight, pharmacological parameters must also follow similar allometric relationships, and, to this end, basal metabolic rate is used as the universal scaling factor. This method of dose extrapolation provides a relatively smaller dose for large animals and a higher dose for small animals. A specific method for interspecies extrapolation of drug dosages used in the zoological medicine field is metabolic scaling as described by Sedgwick and others (Dorrestein, 2000; Mortenson, 2001; Sedgwick, 1993; Sedgwick and Borkowski, 1996). All species are placed in one of five groups, termed *Hainsworth's energy groups:*

passerine birds, nonpasserine birds, placental mammals, marsupial mammals, or reptiles. Using a predetermined K value, a specific minimum energy cost (SMEC) value is calculated and the ratio of the target species SMEC to the SMEC of a safe effective dose in a known species is calculated to achieve that appropriate dosage regimen (Dorrestein, 2000; Mortenson, 2001; Sedgwick, 1993; Sedgwick and Borkowski, 1996). This method is simple in that the metabolic rate can be estimated for most species and applied to any pharmaceutical agent. A known drug dosage is multiplied by the ratio of metabolic rate of a known, similar species and the new species. Unfortunately, this method has not been well validated and several pharmacological papers have illustrated specific failures in this method of extrapolation.

The allometric approach is to measure a pharmacokinetic parameter in multiple species and to plot the data against weight to derive a new allometric equation that can be used to estimate the pharmacokinetic parameter in an unknown species. Similar to its use for selecting the first time dose in humans (Boxenbaum and DiLea, 1995), interspecies extrapolation serves an important function within the framework of veterinary medicine. In this regard, among its uses, it is especially important for estimating an appropriate dose in large animal species for which there does not exist pharmacokinetic or clinical information to support dose estimation. The caveat is that where first dose in humans is a prediction of a safe dose, in zoological medicine, the extrapolated dose in nonapproved species must be *both* safe and efficacious. Despite the potential for extrapolation error, the reality is that allometric scaling is needed across many veterinary practice situations and therefore will be used. For this reason, it is important to consider mechanisms for reducing the risk of extrapolation errors that can seriously affect target animal safety, therapeutic response, or the accuracy of withdrawal time predictions. Based upon this analysis, it appears that inclusion of at least one large animal in the scaling (with or without human data) can improve predictions (Mahmood et al. personal communication). In large animals, correction factors could not be applied because there was no trend seen between the exponents of the simple allometry and the appropriate correction factor for improving our predictions (Mahmood et al. personal communication). In addition, the vast majority of large animals for which pharmacokinetic data are available are herbivores. Conversely, the smaller animal species are either omnivores (mouse, rat, monkey, and human) or carnivores (dogs and cats). This difference in feeding behavior itself can influence drug metabolism and renal elimination. While large carnivore data (lion, tiger, polar bear, etc.) would be helpful, the obvious dangers hinder this area of research. Some marine mammal species may be worthy of consideration, but due to body fat composition of species, such as killer whales (*Orcinus orca*), the results would be of limited use. There is little way to predict, a priori, which animal species will be best suited for inclusion in the interspecies predictions. Another point of consideration is the interspecies differences in the contribution of various organ systems and differences in body composition as it pertains to the body weight estimates.

All extrapolation methods assume that the route of elimination is similar across all species used in the extrapolation and this is simply not true. The reality is that most drugs, 75% in Riviere's published data (Riviere et al., 1997), are not scalable across multiple species and that allometric scaling of pharmacokinetic parameters, while useful, has limitations. It is necessary, for the best therapeutic outcome, to have pharmacokinetic and efficacy data in each species that is treated in zoological medicine. The use of the available literature to understand the route of elimination and the extent of metabolism of therapeutic agents will greatly assist in determining allometric relationships of pharmacokinetic parameters. This should lead to more realistic and rational design of dosage regimens in zoological medicine.

"No presently available chemical restraint agent is equally effective and safe for use with all 45,000+ vertebrate species" (Fowler, 2008). This statement relates not just to chemical restraint, but to therapeutic use in general within zoological medicine. Changes in minor species drug approval could make it easier for the needed information to get into the hands of veterinarians. The Minor Use and Minor Species Animal Health Act of 2004 (MUMS) has been enacted to address the lack of drug availability for minor species. This includes food animals, companion pets, wildlife, and zoo species. An increase in basic pharmacokinetic parameters in zoological species will increase the therapeutic options for veterinarians. Any pharmacokinetic or pharmacodynamic studies in these species would be welcomed.

Some of the specific needs for zoological medicine are formulations that would allow for administration of therapeutic agents via the drinking water or milled into the feed. Other routes of administration that have not been used to their full extent in zoological medicine are rectal, sustained or controlled release, and topical. Increased information and formulations that would allow for administration of appropriate therapeutic agents would be of great benefit. This chapter brings to light some of the issues that face veterinarians on a daily basis when they deal with nontraditional species. Clearly it is not economically feasible to develop every drug for every species. However, targeted approvals or research could greatly increase the efficacy and safety of current and future therapeutics. Also, this type of approach would increase the quality of care provided to zoological species.

Section 12

Regulatory and Other Considerations

55

The Regulation of Animal Drugs

Steven D. Vaughn and Marilyn N. Martinez

Introduction

This chapter describes the regulatory framework that guides animal drug approval within the US. The regulation of animal drugs is administered by the US Food and Drug Administration (FDA). The FDA is given its authority from the US Congress through the Federal Food Drug and Cosmetic Act (FFDCA). The FFDCA has been amended many times since its original passage in 1938 to provide new and refined provisions, some of which will be discussed in this chapter.

The FDA/Center for Veterinary Medicine (CVM) website is a good reference source to bookmark for keeping abreast of regulatory policies and issues pertaining to the regulation of animal drugs and feeds. The CVM home page can be accessed at: www.fda.gov/AnimalVeterinary. The CVM Homepage also provides links to the Freedom of Information (FOI) summaries for approved New Animal Drug Applications (NADAs), Supplemental NADAs, and Abbreviated New Animal Drug Applications (ANADAs). These summaries provide valuable information on the data submitted to support the approval of the application. The website also hosts a searchable database: Animal Drugs @ FDA.

The availability of approved new animal drugs for use in livestock, poultry, pets, and other animals is vital to protecting the health of animals, increasing the efficiency of food production, and to protecting the health of humans who consume the products of food-producing animals. Appropriate use of animal drugs also enhances human health through prevention of zoonotic disease transmission and protection of the food supply. With regard to companion animals, healthy pets enhance the quality of human life through the human–animal bond. Practical application of the principles of pharmacology is important for development of safe and effective animal drugs and for making the best use of these products during clinical practice. An understanding of considerations and regulatory constraints that guide the evaluation of veterinary pharmaceutical products by the FDA is vital for optimizing the animal drug development process and for using label information to customize treatments to match patient needs.

Drugs versus Biologics versus Pesticides

Animal products are regulated by several agencies. These agencies work together to determine which regulatory authority is the best fit for a particular animal product. The intent of this cooperation is to ensure consistency and equity in the regulation of animal products and to avoid animal products being regulated by multiple authorities and under different laws. FDA/CVM regulates the manufacture and distribution of drugs, food additives, and medical devices used in veterinary species. This includes both product approval and postapproval monitoring to ensure continued product safety and effectiveness.

Animal Drugs

Section 512 of the Federal Food Drug and Cosmetic Act (FFDCA) provides the statutory provisions governing the regulation of animal drugs. Through this act, a new animal drug is considered to be unsafe unless there is in effect an approval of a New Animal Drug Application (NADA) and unless the use of a drug and its labeling conform to the approved application. Any drug that is deemed unsafe is considered to be adulterated within the meaning of the FFDCA.

Device

A device is an instrument, apparatus, implement, machine, contrivance, implant, in vitro reagent, or other similar or related article, including any component, part, or accessory, which is intended for use in the diagnosis

of disease or other conditions, or in the cure, mitigation, treatment, or prevention of disease, in man or other animals, or intended to affect the structure or any function of the body of man or other animals, and which does not achieve any of its principal intended purposes through chemical action within or on the body of man or other animals and which is not dependent upon being metabolized for the achievement of any of its principal intended purposes. Currently, there are no FDA premarketing approval requirements for medical devices intended for animal use. However, veterinary medical devices are subject to the general provisions of the Act that relate to misbranding and adulteration. (Sections 501 and 502 of the FFDCA).

Veterinary Biologics

The US Department of Agriculture, Animal and Plant Health Inspection Service, Veterinary Services, Veterinary Biologics regulates veterinary biologics (such as vaccines, antitoxins, and diagnostics that are used to prevent, treat, or diagnose animal diseases) under authority of the Virus Serum Toxin Act of March 4, 1913. The FDA and USDA work together through a Memorandum of Understanding to determine whether a product will be regulated as an animal drug or as a veterinary biologic. The regulations covering veterinary biologics may be found in Title 9 of the Code of Federal Regulations.

Pesticides

The Environmental Protection Agency regulates pesticides (including preparations for use on inanimate objects, rodenticides, and most insecticides) are regulated by the EPA under the authority of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). The FDA and EPA work together through an informal agreement to determine whether a product will be regulated as an animal drug or a pesticide. Title 40 of the Code of Federal Regulations contains the regulations under which pesticide programs operate.

What is a New Animal Drug?

A product is determined to be a new animal drug by its intended use. An animal drug is a product intended for use in animals for the diagnosis, cure, mitigation, treatment or prevention of disease, or a product other than food, intended to affect the structure or any function of the body of animals. This includes any drug intended for use in animal feed but not including the animal feed. If the animal drug's composition is such that the drug is not generally recognized as safe and effective for the use under the conditions prescribed, recommended, or suggest in the labeling of the drug (21 U.S.C. § 321(v)) and some other criteria, it is deemed to be a new animal drug. Virtually all animal drugs are "new animal drugs" within the meaning of the FFDCA, and are therefore subject to Section 512 of the FFDCA.

As mandated by the FFDCA (the Act), a new animal drug may not be introduced into interstate commerce unless it is:

- the subject of an approved new animal drug application (NADA), or
- the subject of an abbreviated NADA (ANADA), or
- the subject of a conditional approval (CNADA) pursuant to 21U.S.C. §360ccc or
- there is an index listing in effect pursuant to 21 USC § 360ccc-1 (21 U.S.C. §§ 331(a) and 360b(a)).

Under section 512(j) of the act, new animal drugs may be exempt from the approval requirements of the act if they are intended solely for investigational use to evaluate the safety and effectiveness of the drug.

Laws, Regulations, and Guidance

The FDA is authorized by the US Congress to implement certain laws. For example, the predominant statutory authority for FDA to regulate animal drugs is the Federal Food, Drug, and Cosmetic Act. Other laws, such as the Environmental Policy Act, are also used by the FDA. The FDA further interprets these laws by promulgating federal regulations. These regulations have the force of law and are used to further ensure that the intent of Congress is followed. These regulations are published in the Code of Federal Regulations (CFR). The section of the CFR addressing the regulation of new animal drugs is Chapter 21. The FDA will often issue other documents, known as guidance, that provide the Agency's current thinking on a particular subject. These guidance documents are not legally binding on the Agency or a drug sponsor but are helpful in describing to a sponsor how to approach addressing a statutory requirement. Guidance documents are available on the FDA website.

History of the FDA and its Relationship to Veterinary Medicine

Although veterinarians have been a part of the FDA since it was formed in 1927, regulation of veterinary pharmaceuticals was not initiated until the 1950s. When the FDA was divided into five Bureaus in 1954, a branch dedicated to the evaluation of veterinary medicine was created within the Bureau of Medicine. This branch became

Table 55.1 Historical overview of the US FDA. Source: US Food and Drug Administration.

1848: Import Drugs Act (first Federal statute for guaranteeing quality of medicines).
1862: President Lincoln created the Department of Agriculture (USDA).
1880: After a year's investigation into food and drug adulteration, USDA began advocating enactment of a national food and drug law.
1906: First Federal Food and Drug Act was signed into law and was administered by USDA's Bureau of Chemistry after studying food and drug adulteration.
1927: The Food, Drug, and Insecticide Administration was formed.
1938: Due to deaths from a sulfanilamide elixir containing an antifreeze analogue, the Federal Food, Drug, and Cosmetic Act (FFDCA) was enacted, requiring manufacturers to provide evidence of product safety.
1951: Durham-Humphrey Amendment initiated prescription requirements for certain human drugs. The veterinary Rx legend was effected through rulemaking.
1953: The FDA was transferred to the Department of Health, Education and Welfare.
1954: The FDA was organized into five Bureaus, including a Bureau of Medicine, within which was a Veterinary Medical Branch.
1959: The Veterinary Medical Branch became a Division due to extensive use of animal drugs and medicated feeds.
1962: Kefauver-Harris Drug Amendments resulted from the thalidomide disaster, requiring that drugs show both safety and effectiveness, and establishing GMPs.
1965: The Bureau of Veterinary Medicine (BVM) was established.
1984: The BVM became the Center for Veterinary Medicine (CVM).

a bureau of its own in 1965, and, in 1984, the Bureau of Veterinary Medicine became the current Center for Veterinary Medicine (CVM). A brief chronology of FDA history is provided in Table 55.1. Additional information on the history and current responsibilities of the FDA and CVM is available on the website (www.fda.gov).

Other Important Amendments to the FFDCA

Generic Animal Drug and Patent Term Restoration Act

On November 16, 1988, the President signed into law the Generic Animal Drug and Patent Term Restoration Act. The new law, known as GADPTRA, amends the Federal Food, Drug, and Cosmetic Act to provide for the approval of generic copies of animal drug products that have been previously approved and shown to be safe and effective when used in accordance with their labeling. Under GADPTRA, a generic animal drug product may be approved by providing evidence that it has the same active ingredients, in the same concentration, as the approved animal drug product, and that it is bioequivalent to the approved animal drug product.

The GADPTRA provides for a period of 3 years of marketing exclusivity for a new use of an animal drug (a use that required reports of new clinical or field investigations for its approval), during which time no abbreviated application for a generic copy may be approved for the new use. The law also provides for a period of 5 years of marketing exclusivity for an animal drug that has not been previously approved in any new animal drug application. During this period, no abbreviated application may be submitted. (Exception: An abbreviated application may be submitted after 4 years if the generic applicant claims noninfringement of a listed patent that is claimed for the approved product or its use.) The law also provides for another form of marketing exclusivity, known as patent term restoration. This type of exclusivity extends the period of protection by US patent for an animal drug, or its method of use, that was approved after November 16, 1988, to compensate for the time that was required for investigation and regulatory review of the animal drug prior to its approval. Patent term restoration is not related to the exclusivity periods described above and may overlap those exclusivity periods.

The information necessary to obtain approval to market a generic animal drug is submitted to FDA in the form of an Abbreviated New Animal Drug Application (ANADA). The application must provide certification by the applicant that a patent does not exist, that a patent has expired or will soon expire, or that a patent claimed for the approved product is invalid or will not be infringed upon by approval of the abbreviated application. In the latter case, the generic applicant or sponsor must then notify the sponsor of the approved product application and the owner of the patent that he or she has filed an abbreviated application claiming invalidity or noninfringement of the patent.

All animal drugs that were approved for safety and effectiveness on November 16, 1988, or have been approved since that date, and are not protected by patent or exclusivity are eligible for copying under the provisions of the GADPTRA, unless the animal drug has been subsequently withdrawn from the market for safety or effectiveness reasons, or unless it is the subject of a Notice of Hearing that has been published in the Federal Register. To meet requirements of the GADPTRA, the Center for Veterinary Medicine has arranged for the publication of a list of animal drug products that are eligible to be copied as generics (Green Book).

The Animal Medicinal Drug Use Clarification Act of 1994

The Animal Medicinal Drug Use Clarification Act (AMDUCA) enabled veterinarians for the first time to use a human or animal drug in an extralabel manner under certain conditions. Prior to the enactment of the AMDUCA of 1994, the FFDCA prohibited veterinarians from prescribing new animal drugs for any indications other than the specific conditions of use on the approved labeling. This extralabel use restriction precluded veterinarians from using an approved new animal drug for an unapproved animal species, for an unapproved indication, or for an approved species at dosage levels higher than that stated on the label. Prior to 1994, the use of human drugs for treating animals was also illegal.

In 1996, Title 21 of the CFR was amended to add part 530, entitled *Extra-label Drug Use in Animals*. This action served to implement AMDUCA to permit veterinarians to prescribe extralabel uses of certain approved animal and human drugs to treat animals under certain conditions. These regulations gave veterinarians the flexibility to meet patient needs in the practice of veterinary medicine.

Under AMDUCA, the key constraints are that any extralabel use must be by or on the order of a veterinarian within the context of a veterinarian–client–patient relationship; the use must not result in violative residues in food-producing animals; and certain listed compounds are prohibited from extralabel use in food-producing animals. The Agency may establish safe and violative levels for residues for extralabel use and may require development of analytical methods for residue detection. If, after affording an opportunity for public comment, FDA finds that an extralabel animal drug use presents a risk to public health or that no analytical method has been developed and submitted, the Agency may prohibit the extralabel use.

As of this writing, the Agency has prohibited the extralabel use of the following drugs in food-producing animals:

1) Chloramphenicol;
2) Clenbuterol;
3) Diethylstilbestrol (DES);
4) Dimetridazole;
5) Ipronidazole;
6) Other nitroimidazoles;
7) Furazolidone;
8) Nitrofurazone;
9) Sulfonamide drugs in lactating dairy cattle (except approved use of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine);
10) Fluoroquinolones;
11) Glycopeptides;
12) Phenylbutazone in female dairy cattle 20 months of age or older;
13) Cephalosporins (not including cephapirin) in cattle, swine, chickens, or turkeys:
    a) for disease prevention purposes;
    b) at unapproved doses, frequencies, durations, or routes of administration; or
    c) if the drug is not approved for that species and production class.
14) The following drugs, or classes of drugs, that are approved for treating or preventing influenza A, are prohibited from extralabel use in chickens, turkeys, and ducks:
    a) Adamantanes
    b) Neuraminidase inhibitors.

Neither AMDUCA nor the implementing regulations lessen the responsibility of the manufacturer, the veterinarian, and the food producer to prevent risks to public health from drug residues in animal-derived foods. Updates on issues pertaining to the Animal Medicinal Drug Use Clarification Act of 1994 and its implementation by CVM can be found at: www.fda.gov.

The Animal Drug Availability Act of 1996

In an effort to increase the number of animal drugs on the market and to reduce regulatory burdens on the animal health industry without undermining the safety of animal drug products, the Animal Drug Availability Act (ADAA) was signed into law on October, 1996. The current study requirements associated with NADAs reflect changes instituted by this Act. In brief, the ADAA provides for:

- An amendment to the definition of substantial evidence of effectiveness that provided CVM with greater flexibility to make case-specific scientific determinations regarding the number and types of adequate and well-controlled studies that will provide, in an efficient manner, substantial evidence that a new animal drug is effective.
- Greater direct interaction between animal drug sponsors and the FDA during the drug development process. The law requires a presubmission conference, held at the sponsor's discretion, to discuss the drug development at its earliest stages. The goal is for the FDA and the manufacturers to reach a common understanding regarding what data will be needed to establish safety and effectiveness, and what types of studies can be conducted to generate such data.
- The ability to market an animal drug with a range of acceptable/recommended doses on animal drug product labeling, rather than as one optimum dose. In addition, the law directs FDA to broaden the approval

process to make available more animal drugs to treat minor species.

- A new category of drugs, "Veterinary Feed Directive Drugs" (VFD), that allows approval and use of new animal drugs in animal feed, on a veterinarian's order, while incorporating safeguards to ensure the safe use of such drugs. This new category of drug is discussed in Section Classifying Prescription, Over-the-Counter and Veterinary Feed Directive Animal Drugs.

Premarket Evaluation of New Animal Drugs

In 1968, the US Congress passed the animal drug amendments to the Federal, Food, Drug, and Cosmetic Act. In doing so, Congress recognized the need for the use of animal drugs to meet therapeutic and production needs for animals. Congress intended to create a structure that would enable the approval of new animal drugs that met the legal standards of safety and effectiveness.

In order to approve and sustain a new animal drug for commercial use, four critical pillars must be met. First, an animal drug product must be *safe*, safe for the animal, safe for the humans consuming food derived from treated animals, safe for the user or the person administering the drug and for the environment. Second, an animal drug must be *effective* for its intended uses. These uses are those prescribed, recommended, or suggested in the labeling of the product. Third, the animal drug must be a *quality manufactured product***,** being the result of a validated manufacturing process conducted in accordance with current Good Manufacturing Practice regulations. Fourth, the product must be *properly labeled* to inform the user of the product not only how to use the product but also safety considerations, residue withdrawal procedures, and storage and handling procedures. When these four characteristics are met, an animal drug can be approved for marketing. Once in the market place, an animal drug is monitored to ensure that these characteristics are sustained.

From CVM's perspective, its public health mission is achieved when a safe, effective, quality manufactured, properly labeled new animal drug is put in the hands of the user. Animal owners and veterinarians have many options for products that they might choose to use in treating animals under their care. Some of these options include unapproved drug such as illegal drugs, counterfeit drugs, or illegally compounded drugs. Each of these options fails to meet the characteristics of an animal drug that protects public and animal health. CVM and animal drug sponsors share a mutual interest in putting approved animal drugs in the hands of the user. CVM has an important responsibility to ensure that only safe, effective, quality manufactured, and properly labeled new animal drugs are in the marketplace for use and unsafe and ineffective products are not present.

Animal drugs are used to meet therapeutic and production needs for animals for a large number of animal species and indications. Consider that in the United States there are, 9 billion chickens, 262 million turkeys, 97 million cattle, 62 million pigs, 6.2 million sheep, and millions of aquaculture animals, and over 280 million pets in the USA, including 88 million cats and 75 million dogs.

For companion animals, CVM wants to ensure and increase the level of high-quality medical care for companion animals as well as improve the quality of life through medical interventions. Pets in the United States are closely bonded to their human owners. As such, many pets have significant close interactions with their owners presenting ideal opportunities for disease transmission. Many therapeutic drugs for companion animals serve an important human public health purpose preventing the development of zoonotic diseases when they are used in pets. Many companion animals serve an important role in their relationship with humans in terms of the wellness of people being directly linked to the human–animal bond. Healthy pets mean healthier people.

For food-producing animals, CVM wants to ensure that the use of therapeutic and production animal drugs maintain the health and improve animal welfare. In addition, by improving animal health and production, these animal drug products work to increase the availability of an affordable, abundant, and wholesome food supply to meet the needs of a growing human population. One of CVM's challenges is to engage in the development and evaluation of new animal drugs, especially new innovative technologies, to meet the demand for increased safe, affordable, and abundant food production.

For the animal drug industry to produce an adequate and diverse supply of animal drugs to meet therapeutic and production needs for animals, the regulatory processes must be constructed to not only meet the statutory requirements but also to be efficient and conducive to the further development of new animal drugs. At first look, these statements may seem contradictory and, at times, do cause substantial discussions. However, they are independent characteristics. CVM must first and foremost ensure that new animal drugs are safe and effective. CVM must prevent the introduction of unsafe and ineffective drugs into the marketplace as well as remove those that exist in the marketplace. At the same time, CVM must have efficient processes that are responsive to its stakeholders needs. This includes timely review decisions, effective and timely communication, and effective project management.

Without a doubt, the development and marketing of a new animal drug in the United States is a complex and onerous undertaking. Meeting the rigorous standards for safety and effectiveness and sustaining a quality manufactured product is a challenge. Having an approved new animal drug ensures protection for animals, the public, and drug manufacturers. By having consistent and equitable standards, sponsors are assured that competitors will have to meet essentially the same regulatory standards. Moreover, by providing a seal of approval that distinguishes the approved product from unapproved, illegal, counterfeit, and illegally compounded competing animal drug products, consumers of animal drug products have the assurance of a quality, reliable product.

The process leading to the approval and marketing of a new animal drug product is, in some respects, similar to that associated with human pharmaceuticals. In fact, many animal drugs were initially developed for potential use in humans. However, veterinary pharmaceutical development creates complexities that are not faced by our human pharmaceutical development. Some of these issues are:

- the diversity in size, behavior, metabolic needs, and lifespan between animal species;
- species and breed differences in both pharmacokinetic and toxicity profiles;
- a wide spectrum of disease agents that produce different disease manifestations under different conditions;
- a range of husbandry practices, which include the array of settings in which animals are kept – ranging from animal companions in the home to large livestock operations;
- inability to communicate directly with the animal patient;
- public health concerns, including environmental safety, human food safety, and the potential influence of veterinary antimicrobial use on development of resistance in bacteria of concern to both veterinary and human medicine.

There are also differences in the use of drug products in food-producing animal species versus companion animal species. The focus of diagnostics, drug therapy, and monitoring of treatment response is on the individual companion animal. The goals of therapy are to prevent, treat, or manage a disease or to improve the quality of life for the individual animal. Some therapies may be continued throughout the life of the companion animal. For food-producing animals, the focus is generally on the health of an entire group (herd or flock) of animals instead of an individual animal. Although food-producing animals may be individually dosed using injectable or topical products to treat or control certain diseases, group dosing via medicated drinking water or feed is often used in order to minimize handling stress and to allow for a more efficient means of dosing a large number of animals during a disease outbreak. The goal in food animal medicine is to manage the health of the herd.

A further challenge to animal drug development is the low cost and narrow profit margin of veterinary pharmaceuticals. Based upon information contained on the Animal Health Institute (AHI) website (http://www.ahi.org/about-animal-medicines/industry-statistics/), it takes about 7 to 10 years and up to $100 million to develop a new major animal drug product. On the average, when it comes to animal drug products, it is estimated that on an international front, the expenditure is only about 1/40th of what is spent on human medicine. In this regard, within the US, the sales associated with animal pharmaceuticals were between $5 and 6 billion (2010 estimates). In contrast, the total value of US consumption of pharmaceutical drugs in 2009 was $300 billion (http://www.bls.gov/ppi/pharmpricescomparison.pdf). Based upon information on the PhRMa website, annual pharmaceutical expenditure over the years 2009–2011 was estimated to be approximately $50 billion. In 2012, the amount of sales reinvested into research and development was 20.7% (http://phrma.org/sites/default/files/pdf/PhRMA%20Profile%202013.pdf).

The limited opportunity for cost recovery forms a barrier to increasing the availability of new animal products. As a practical matter, the amount of data contained in a New Animal Drug Application (NADA) is substantially less than that submitted to support a New Drug Application (NDA) for human use. For example, the number of patients enrolled in clinical trials of new animal drugs is substantially smaller than the thousands of patients generally enrolled in trials submitted in support of human NDAs.

Despite these constraints, the same statutory requirements regarding the demonstration of product safety and effectiveness apply to the regulation of both human and veterinary drug products. Therefore, innovative application of the principles of pharmacology and research study design is important in meeting the challenge of developing cost-effective ways to generate the data necessary to meet the statutory requirements of the FFDCA. Pharmaceutical companies are encouraged to consult closely with CVM to develop study designs and assays that maximize the value of the collected data to support their drug applications.

Components of New Animal Drug Applications

The legal requirements for NADAs are detailed in 21 CFR §514.1. Required information for evaluation of the NADA is grouped into technical sections and includes:

- Target Animal Safety;
- Effectiveness;
- Human Food Safety;
- Chemistry, Manufacturing, and Controls;
- Environmental Impact;

- All Other Information;
- Labeling.

The Office of New Animal Drug Evaluation (ONADE) within CVM is responsible for the review of information submitted by drug sponsors to obtain approval to manufacture and market animal drugs. Highlights for each of these technical sections are provided in the next several sections of this chapter.

Target Animal Safety

The purpose of the Target Animal Safety (TAS) studies is to evaluate potential harmful effects associated with use of a new animal drug in a controlled setting, as a prediction of product safety in the larger patient population. The regulation for TAS, 21 CFR §514.1(b)(8)(i), requires "adequate tests by all methods reasonably applicable to show whether or not the new animal drug is safe and effective for use as suggested in the proposed labeling". The target animal safety section may include studies that identify the toxic syndrome(s) associated with the drug and the margin of safety for use of the product in the treated animal. The FDA has guidance documents to summarize recommendations and suggestions for efficiently carrying out these studies.

As with human pharmaceuticals, published literature, preliminary studies (including pharmacokinetics and pharmacodynamics, and extrapolation from toxicity testing in laboratory animals), and safety observations in clinical effectiveness trials are considered in the safety evaluation. But for new animal drugs, safety is also directly assessed in the target species through laboratory-based (overdose) studies. These nonclinical laboratory studies must be conducted in accordance with Good Laboratory Practices (GLP) regulations (21 CFR Part 58). FDA does not require that domestic animals be maintained under the conditions required for laboratory animals during GLP testing. Although clinical effectiveness studies contribute data to the overall safety assessment of a drug, GLP regulations do not apply to clinical studies. Furthermore, the product evaluated in the TAS studies should be the same as the product intended to be marketed, that is the same chemical, same particle size, and formulation, and manufactured in conformity with the principles of Good Manufacturing Practices (GMP).

Although the specific information needed to assess TAS in a particular NADA depends on a variety of factors (e.g., proposed usage regimen and dose, type of drug, pharmacokinetics, chemistry and manufacturing considerations, claims, previous use history, and animal species including class and breed), the underlying scientific approach, as outlined in FDA guidance documents, is common to all. Studies generally compare healthy control animals with small numbers of healthy animals of the target species treated with multiples of both the recommended dose and duration of administration of the product. Appropriate observations, physical examinations, clinical pathology tests (hematology, blood chemistry, urinalysis, fecal analysis, etc.), necropsy, and histopathology should be conducted to identify possible adverse effects. Additional specialized studies, such as evaluation of injection sites, topical administration sites, reproductive safety and mammary gland safety, may be needed depending on the conditions of use and the characteristics of the drug. There may also be additional species-specific study requirements based upon unique physiologies and or husbandry practices. For example in fish, target animal safety can change as a function of water temperature, ionic strength and composition, and life stage (Storey, 2005).

Effectiveness

The availability of certain approved new animal drugs for use in livestock, poultry, pets, and other animals is vital to protecting the health of animals and the health of humans who consume the products of food-producing animals. The availability of other approved new animal drugs is vital to increasing the efficiency of food production in the United States. The changes made to the definition of "substantial evidence" by the ADAA and by the further definition of that term provided CVM with greater flexibility to make case-specific scientific determinations regarding the number and types of adequate and well-controlled studies that will provide, in an efficient manner, substantial evidence that a new animal drug is effective.

One or more adequate and well-controlled studies are required to establish, by substantial evidence, that a new animal drug is effective. These studies are intended to demonstrate that a new animal drug is effective for each proposed intended use and the associated conditions of use. The intended use includes the dose or dose range, frequency, duration, timing (e.g., in relation to the onset of clinical signs), animal species, age, gender, class, and breeds of animal for which the new animal drug is intended for use. Subsequent to the enactment of the ADAA, the number of adequate and well-controlled studies for providing substantial evidence of effectiveness depends upon the number of intended uses, how narrowly or broadly each intended use is defined, and upon the conditions of use in the proposed labeling. When a proposed therapeutic indication is associated with a dose range, substantial evidence of effectiveness is demonstrated for the lowest proposed dose. Sponsors also need to justify the intended dose. The basis of this justification can include pharmacokinetic/pharmacodynamic relationships, literature, and laboratory tests.

The technical section also includes information to support selection of the dosage (called dosage characterization). The pharmaceutical sponsor of the new animal drug may provide a logical scientific rationale or use a variety of studies in developing an effectiveness technical section, including studies conducted in the target species, studies conducted in laboratory animals, field investigations, bioequivalence studies, and in vitro studies. Pharmacokinetic and pharmacodynamic studies may augment and further document the nature of the animal drug's effectiveness. Prior to submission of the major technical sections, or as part of the effectiveness technical section, the sponsor provides the basis for choosing the dosage (dose, duration, and frequency) to be used in effectiveness studies. The sponsor may derive dosage characterization from many sources, including dose titration studies, pilot studies, foreign studies, published literature, in vitro studies, interspecies dose extrapolation, and pharmacokinetic and pharmacodynamic studies. In the dosage characterization submission, the sponsor provides a succinct dosage characterization narrative which is included in the Freedom of Information (FOI) Summary for the product.

The effectiveness section must contain full reports of all studies that show whether or not the new animal drug is effective for its intended use (21 CFR § 514.1(b)(8)(i)). The sponsor must demonstrate by substantial evidence that the drug will have the effect it purports or is represented to have under the conditions of use prescribed, recommended, or suggested in the proposed labeling. 21 CFR §514.4(b)(2) requires that a sponsor submit data generated from well-controlled studies of a new animal drug to distinguish the effect of the new animal drug from other influences, such as spontaneous change in the course of the disease, normal animal production performance, or biased observation. The data provided for substantial evidence of effectiveness must permit qualified experts to conclude that a new animal drug will have the effect it purports or is represented to have under the conditions of use suggested in the proposed labeling (21 CFR §514.4(b)(3)(i)(C)). Generation of these data represents a significant component of drug development time and cost such that the amount and nature of the evidence needed can be an important determinant of whether and when new animal drugs become available to the public.

The effectiveness studies are designed to test the product under actual conditions of use. In contrast to studies conducted under controlled laboratory settings, the clinical trial provides information pertaining to how the product will perform under real world conditions in the patient population. The effectiveness studies are typically designed with a negative (placebo) control or an active control. An active control is an approved product of established effectiveness for the same indications as the proposed product under development, with a known margin of superiority relative to a placebo (Piaggio et al., 2006). The evaluation of the active control study should explain why the new animal drugs should be considered effective in the study, for example, by reference to results in previous placebo-controlled studies of the active control. The study is typically masked, and patients are randomized to treatment groups. In so doing, the investigator can evaluate the drug effects with minimal bias. The study typically follows a multicenter and multiinvestigator design to increase the likelihood that the product will perform as expected in the broader population postapproval. The study is testing whether the product will perform in the hands of multiple investigators under a variety of husbandry conditions, clinical practice settings, across different breeds and ages of the patient populations, and perhaps different stages of the disease or condition. The proposed indication drives the design of the effectiveness study. Likewise, the results of the effectiveness study drive the wording of the indication. The final approved indication and dosage are confirmed by the results of the effectiveness studies. Lastly, the effectiveness studies also provide important safety information about the use of the product in the patient population.

The manufacturing characteristics of the product used in the efficacy study must be provided as part of the study results in order to provide CVM with an assurance that the test article used is representative of the product intended for marketing.

Human Food Safety

The human food safety section is submitted only for applications for new animal drugs intended for use in species that are used for human food (food-producing animals). This section must include a description of practicable methods for determining the quantity, if any, of the new animal drug in or on food, and any substance formed in or on food because of its use, and the proposed tolerance or withdrawal period or other use restrictions to ensure that the proposed use of the drug will be safe (21 CFR § 514.1(b)(7)). This section should also contain any data relating to residue toxicology (including the impact of residues on human intestinal microflora), residue chemistry, and, if the new animal drug has anti-infective properties, microbial food safety.

The human food safety section may include, but is not limited to, short and long-term toxicology studies, total residue and metabolism studies, analytical method validation studies, tissue residue depletion studies, and microbial food safety information.

By the general safety provisions of Sections 409, 512, and 706 of the Federal Food, Drug, and Cosmetic Act, FDA must determine for each food additive, new animal drug, or color additive proposed for use in food-producing animals whether the edible products derived from treated animals are safe for human consumption. Accordingly, the sponsor must demonstrate *reasonable certainty of no harm* to human health for all drug products intended for use in food-producing animals.

A human food safety evaluation focuses on residues that are present in the intended type of food animal following intended use of the drug. A residue is "any compound present in the edible tissues of the target animal which results from the use of the sponsored compound, including the sponsored compound, its metabolites, and any other substances formed in or on food because of the sponsored compound's use" (21 CFR 500.82)

Details regarding human food safety assessments are provided in CVM Guidance #3 *General Principles for Evaluating the Safety of Compounds Used in Food-Producing Animals.*

The information needed to demonstrate human food safety for a NADA generally includes:

Evaluation of carcinogenicity: To establish the safety of veterinary drug residues in human food, a number of toxicological evaluations are recommended, including an assessment of the potential to induce neoplasia. Exposure to residues of veterinary drugs will usually occur at extremely low levels, but for potentially long periods. To ensure that substances that could pose carcinogenic potential at relevant exposure levels are adequately assessed, a number of issues should be considered, including genotoxicity, metabolic fate, species differences, and cellular changes. As part of the human food safety package, sponsors must determine whether or not carcinogenicity testing should be conducted. The decision to undertake carcinogenicity testing should take into consideration: (i) the results of genotoxicity tests, (ii) structure–activity relationships, and (iii) findings in systemic toxicity tests that may be relevant to neoplasia in longer-term studies. It should also take into consideration any known species specificity of the mechanism of toxicity. Any differences in metabolism between the test species, target animal species, and human beings should be taken into consideration.

Toxicological assessment: Toxicology tests are conducted in laboratory animals to determine the dose at which the compound produces an adverse effect and a dose that produces a no observed effect level (NOEL).

Determination of an Acceptable Daily Intake (ADI): The ADI is derived from the results of the study illustrating the most sensitive endpoint in the most appropriate species. The ADI is the highest dose used in the study that demonstrates a NOEL divided by an appropriate safety factor. As a general rule, CVM will use the safety factors indicated below in this section for the various types of studies.

The ADI is estimated as:

$$\text{ADI } (\mu\text{g/kg/day}) = [(\text{NOEL } (\mu\text{g/kg}))/ (\text{Safety Factor } (\text{day}^{-1}))]$$

Table 55.2 Safety factors associated with the different kinds of toxicology investigations

Type of Study	Safety factor
Chronic	100
Reproduction/teratology	(100 or 1000; 100 for a clear indication of maternal toxicity, 1000 for other effects)
90-Day	1000

The appropriate safety factor depends upon the type of study being used for establishing the ADI, as described in Table 55.2.

Determination of a safe concentration: The safe concentration is, by definition, the amount of residue that can be eaten in any edible tissue each day for an entire lifetime without exposing the consumer to residues in excess of the ADI. To estimate the safe concentration, FDA considers the ADI, the weight in kg of an average adult human (60 kg), and the amount of the product that may be consumed in grams per day (where consumption values, in grams consumed per day, are 300 for muscle, 100 for liver, 50 for kidney, and 50 for fat):

$$\text{safe concentration } (\mu\text{g/g}) = \frac{\text{ADI } (\mu\text{g/kg/day}) \times 60 \text{ kg}}{\text{grams consumed per day}}$$

Once a safe concentration has been determined, methods are developed and validated that will allow future testing of animal tissues to monitor for residues. Withdrawal times are determined to allow use of the drug with any residues expected to be below the safe concentration.

Selection of a marker residue: The marker residue is a residue used to monitor the depletion of total residues in edible tissues in a food animal. The marker residue must have a demonstrated relationship with the total radiolabel drug residues such that when the concentration of the marker residue is less than a specific value (the tolerance) in the target tissue, the total residues in all of the edible tissues are less than their respective safe concentrations.

Development and validation of an analytical method to measure the marker residue: This method serves as the regulatory method for determining the withdrawal time and for assessing whether or not animal-derived products contain residue concentrations in excess of the established limit (violative residues of meats and animal-derived food products). This method will be used after a drug is approved by validated analytical laboratories during inspections, insuring the absence of violative residues in marketed human food products derived from animal sources.

Establishment of a tolerance: A tolerance (the FDA maximum concentration of the marker residues within the target tissue) or the European version of a tolerance, the maximum residue limit (MRL) is determined based on the marker residue. The target tissue for the tolerance is generally the edible tissue from which residues most slowly deplete.

Establishment of a withdrawal time: The withdrawal time is the time between the last administered dose and when the drug residues drop below the safe concentration. The regulatory objective of the FDA is to predict a time when we can be 95% certain that the tissue residue concentrations in 99% of the animal population receiving the drug product (when dosed in accordance to the approved product label) will be at or below tolerance. Generally, multiple animals are sampled across at least four time points and regression methods with tolerance limits are used to set the withdrawal time. Concentrations of the marker residue must be measured with the same FDA-approved analytical method that will be used for the regulatory inspections. These topics are also discussed in Chapter 61 of this text.

For antibacterial drugs, additional information is assessed as part of the human food safety section. Two types of potential effects of the new animal drug on bacteria of human health concern are considered (see Section Microbiological Effects on Bacteria of Human Health Concern).

Microbiological Effects on Bacteria of Human Health Concern: The level of antimicrobial residues present in food should not have clinically relevant effects on the human intestinal microflora. Consideration is given to potential microbiological effects on food-borne bacteria of human health concern (FDA/CVM Guidance for Industry #144, Pre-Approval Information for Registration of New Veterinary Medicinal Products for Food-Producing Animals with Respect to Antimicrobial Resistance VICH GL27 and FDA/CVM Guidance for Industry #159 Studies to Evaluate the Safety of Residues of Veterinary Drugs in Human Food: General Approach to establish a Microbiological ADI VICH GL36R). FDA/CVM Guidance for Industry #152 Evaluating the Safety of Antimicrobial New Animal Drugs with Regard to Their Microbiological Effects on Bacteria of Human Health Concern provides guidance for characterization of antimicrobial resistance selection in bacteria of human health concern associated with the use of antimicrobials in food-producing animals. FDA/CVM then uses the resulting risk estimation ranking, along with other data and information submitted in support of the NADA, to determine if the drug is approvable under specific risk management conditions.

Chemistry, Manufacturing, and Controls

The Chemistry, Manufacturing, and Controls technical section is one of the most important as it establishes the identity, strength, and purity of the product as well as the safeguards, unique to approved drugs, that the product will remain the same batch to batch when in commercial production. This enables the user of the product to be able to rely on the data generated in the development of the product to continue to represent the established safety and effectiveness of the marketed product. Several pivotal considerations go into the evaluation of the chemistry and manufacturing of a new animal drug product. These considerations are intended to ensure the quality and performance of the product, both prior to and subsequent to marketing. CVM requires that sponsors provide the information needed to ensure that each lot of the product released to consumers performs in a consistent manner, and that consumers have the necessary information with regard to product storage conditions so that product quality and performance are maintained (21 CFR §514.1).

A full description of the methods used in, and the facilities and controls used for, the manufacture, processing, and packaging of the new animal drug must be provided in the new animal drug application. This description should include full information with respect to any new animal drug in sufficient detail to permit an evaluation of the adequacy of the described methods of manufacture, processing, and packing, and the described facilities and controls. This information is evaluated by CVM's Division of Manufacturing Technologies to determine the identity, strength, quality, and purity of the new animal drug. Information is also needed with regard to the methods used in the synthesis, extraction, isolation, or purification of any new animal drug and the precautions being taken to ensure proper identity, strength, quality, and purity of the raw materials, whether active or not. Sponsors must provide CVM with the instructions used in the manufacturing, processing, packaging, and labeling of each dosage form of the new animal drug, and precautions being taken to ensure batch-to-batch product uniformity.

To ensure adequate performance as the product ages, the sponsor also must conduct studies of the stability of the new animal drug in the final dosage form. Expiry dates represent the duration of time for which product quality and performance can be assured if the product is stored in accordance with label recommendations. The time for expiry is based upon extensive stability testing that is conducted by the drug sponsor on the product intended for marketing, and these data are evaluated by the Division of Manufacturing Technologies at CVM.

Environmental Impact

The environmental impact section must contain either an environmental assessment (EA) under 21 CFR § 25.40, or a request for categorical exclusion under 21 CFR § 25.33 (21 CFR § 514.1(b)(14)). Environmental information is submitted to comply with the National

Environmental Policy Act (NEPA). Before approving a new animal drug, the agency must consider potential effects on the environment. In many cases, including those for many intended uses for minor species, a categorical exclusion from the need to provide an EA can be granted. In other cases, such as new chemical entities, and almost always in the case of a drug for an aquatic species approval, some type of EA will be necessary to support a “finding of no significant impact” (FONSI). The environmental assessment may include information on the introduction of the drug into the environment through manufacture, use, and disposal, the fate of the drug in the environment, and the effects of the drug in the environment.

Environmental documentation addresses the potential impact of the manufacturing and use of the product if the application were approved. The FDA Environmental Assessment Technical Handbook is available through the National Technical Information Service to assist in determining the contents of environmental documents. GLP compliance is required for all environmental laboratory studies. Preapproval GMP inspections are used to confirm the contents of environmental documents that apply to manufacturing environmental permits and controls.

The overall target of the assessment is the protection of ecosystems. The field of ecotoxicology is a complex science and gaps in data and knowledge exist. Nevertheless, CVM and the International Veterinary Cooperative and Harmonization (VICH) have developed guidance (CVM Guidance #166 dated 1/09/2006) that describes the kinds of information needed as part of the Environmental Impact Assessment (EIA) of veterinary medicinal products (VMPs).

The goal of the EIA is to assess the potential for VMPs to affect nontarget species in the environment, including both aquatic and terrestrial species. It is not possible to evaluate the effects of VMPs on every species in the environment that may be exposed to the VMP following its administration to the target species. The taxonomic levels tested are intended to serve as surrogates or indicators for the range of species present in the environment. Impacts of greatest potential concern are usually those at community and ecosystem function levels, with the aim being to protect most species. However, it may be important to distinguish between local and landscape effects. There may be some instances where the impact of a VMP at a single location may be of significant concern, for example, for endangered species or a species with key ecosystem functions. These issues are handled by risk management at that specific location, which may even include restriction or prohibition of use of the product of concern in that specific local area. Additionally, issues associated with cumulative impact of some VMPs may be appropriate at a landscape level.

The route and quantity of a VMP entering the environment determines the risk assessment scenarios that are applicable and the extent of the risk assessment. The EIA is based on the accepted principle that risk is a function of the exposure, fate, and effects assessments of the VMP for the environmental compartments of concern. While emission can occur at various stages in the life cycle of the product, with the exception of certain topicals or those added directly to water, most VMPs first pass through the animal to which it is administered. Generally, the most significant environmental exposure results from excretion of the active substance(s).

All Other Information (AOI)

The All Other Information technical section includes all information pertinent to the review of safety and effectiveness received or otherwise obtained by the applicant from any source (see 21 CFR § 514.1(b)(8)(iv)). The AOI technical section is usually submitted to the CVM ONADE Target Animal Division when the last major technical section is submitted for review and contains information from any investigations, foreign marketing, and scientific literature, and any other data that were not already submitted by the sponsor as part of a major technical section.

This information should be comprehensive and balanced and include favorable and any unfavorable literature. Although this technical section is submitted towards the end of the drug approval process, the sponsor should also submit AOI with each technical section. For example, the effectiveness technical section would include not only dosage characterization and substantial evidence data but also any AOI available at that time. Then when the final AOI technical section is submitted, it would contain only new information identified since the Effectiveness technical section was considered complete.

Product Labeling

The ability to interpret and understand drug labels is essential in ensuring that use of a particular drug achieves the intended outcome and minimizes unintended effects. The product labeling is the avenue through which CVM communicates instructions about product use and storage conditions to veterinarians, as well as communicating the benefits and risks associated with the use of a drug product.

Section 201K of the FFDCA defines “label” as a display of written, printed, or graphic matter upon the immediate container of any article. A drug’s “labeling” includes all labels and other written, printed, or graphic matter, such as package inserts, on the drug, its containers or wrappers or accompanying the drug. Labeling information is derived from studies submitted by the pharmaceutical sponsor to the FDA to support new animal drug approval and is developed as a collaboration between FDA and the drug sponsor.

Throughout the product label, the FDA provides the practitioner with a thorough understanding of the benefits and risks associated with the use of a drug product in the animal patient. The concept of "safe use" includes safety to the animal patient, safety to the person administering the product, the safety of food derived from the treated animal, and environmental safety issues associated with use or disposal of the product. Safety information on the labeling can be derived from studies conducted by the pharmaceutical sponsor, studies from peer reviewed scientific literature, or from extrapolation from human drug labeling information that reasonably applies to the target species.

Safety information is provided throughout the package insert under several different headings, including Contraindications, Warnings, Precautions, Adverse Reactions, and Animal Safety. The labeling is evidenced-based information, and does not represent opinions or conjecture. Therefore, for the practitioner to fully understand how the animal drug will perform, the practitioner should become familiar with all sections of the package insert to better understand both the risks and benefits associated with use of the product. The safety information can be viewed from the perspective of a hierarchy of severity, with Contraindications being the most serious, followed by Warnings and Precautions. The Animal Safety section is generally derived directly from laboratory target animal safety studies. The Adverse Reactions section is developed directly from the preapproval field effectiveness studies and the postapproval experience after the drug is marketed to the larger population. The Contraindications, Warnings, and Precautions statements can be modified by new findings from the postapproval surveillance of product use.

Typical sections/information found on a package insert includes:

- **Product Identification, Description and Prescription Legend** provides the product's brand name (often indicated by "®"), the generic name (the name given to the chemical entity), the dosage form (e.g., tablet, sterile solution, oral suspension, etc.), and if designated as a prescription or VFD drug, the prescription or VFD legend. The labeling for all veterinary prescription products contains the following statement: "Caution: Federal law restricts this drug to use by or on the order of a licensed veterinarian." The prescription (Rx), over-the-counter (OTC), and VFD classification is discussed later in this chapter.
- **The Indications section** of the labeling lists the specific disease(s) or conditions(s) for which a particular drug product is approved. The specific wording in this section depends upon the data contained in the effectiveness technical section of the approved new animal drug application.
- **The Contraindications section** defines the known circumstances under which a product should not be used because the risk associated with drug use clearly outweighs the possible benefit. Contraindications are based upon reasonable evidence that a drug caused a specific adverse reaction. Use of the drug in the situations described in the Contraindications section is likely to result in a serious adverse event that is fatal, or life-threatening, or requires professional intervention, or causes an abortion, or stillbirth, or infertility, or congenital anomaly, or prolonged or permanent disability or disfigurement to the treated animal.
- **The Warnings section describes** serious adverse reactions and potential safety hazards to the animal being treated. Although the adverse reactions may be serious, FDA has determined that the benefit of using the drug outweighs the risk of the adverse event.

The Warnings section may also describe potential actions that could be taken by the veterinarian to mitigate the adverse reaction should it occur, or to decrease the likelihood of the adverse reaction occurring, such as avoiding use in a predefined high-risk population. Warning statements are based upon evidence indicating an association of a serious hazard with a drug, but not necessarily proof that the drug caused the reaction. Significant problems that may lead to death or serious injury may require a "boxed warning" on the package insert.

The Warnings section may also include a user safety (Human Warnings) or human food safety section. The user safety section provides information regarding hazards to human health by contact, inhalation, ingestion, injection, or by other exposure to the product. The human food safety (Residue Warnings) section states the withdrawal time for use of the product in a food animal species. The withdrawal time is the time interval between the last administration of the drug to the food animal and the time when the animal can be slaughtered, or products, such as milk or eggs, can be used for food, without incurring violative drug residues in the food product. This section also warns against use of the drug in animals for which a withdrawal time has not been determined.

- The **Precautions** section includes additional information to enhance the safe use of the product by the practitioner. The Precautions section includes any additional information that is important for the safe use of the product that has not been included in the Contraindications or Warnings sections. The Precautions section may include recommendations for screening or diagnostic tests, information about drug to drug interactions, carcinogenesis, reproductive safety, adverse reactions in species other than the target species, or use in particular subpopulations of the target species, such as pediatric, geriatric, or animals with a particular disease.

- The **Adverse Reactions** section of the labeling lists undesirable effects reasonably associated with the use of the drug that may occur as part of the pharmacological action of the drug or that may be unpredictable in their occurrence. The Adverse Reactions section is developed from the field effectiveness studies conducted by the pharmaceutical sponsor to support new animal drug approval. This section may also include a postapproval experience section, reporting any additional undesirable effects reported from the postapproval surveillance of the product in the larger population. The Adverse Reactions section includes a toll-free number for the practitioner to call for technical assistance from the pharmaceutical sponsor.
- The **Information for Owner or Person Treating Animal** section contains specific information for the owner or person treating the animal regarding the safe and effective use of the product. This information is designed to be conveyed by the prescribing veterinarian to the animal owner. Some products have a separate client information sheet (CIS) in addition to the package insert. The CIS sheet is designed to be given to the animal owner every time the product is dispensed. The CIS is typically required by the FDA when there is a need to give the animal owner detailed information about the potential for serious adverse reactions from the drug. The CIS may include information to help the animal owner recognize and report to the veterinarian any early signs of problems following the use of the product in the individual patient.
- The **Clinical Pharmacology** section is a concise summary of the pharmacology, pharmacokinetics, and pharmacodynamics of the drug in the target species. This section may also provide information about the drug class, potential drug–drug interactions, and the effect of food on product bioavailability. For an antimicrobial agent, this section often includes a microbiology section with susceptibility data for the specific pathogens for which the product is approved.
- The **Effectiveness** section of the package insert contains an abstract of the results from the effectiveness studies published in the FOI Summary. The abstract provides a concise summary of the pivotal effectiveness studies and includes information such as the number and geographic location of study sites, the age, sex, and total number, etc. of animals in the study, a brief description of the study design, and the study results. The abstract describes how the effectiveness studies were conducted and how well the treated animals fared as compared to the control animals. This information can be considered from the perspective of the similarity between the study population versus the potential patient undergoing treatment (where the "patient" can represent an individual animal or a group of animals). For example, relevant questions may include whether or not the patient and the study population are of a similar age, class, and level of morbidity. This kind of information may be particularly useful when choosing between similar products that are approved and available for the same indications.

With regard to the database supporting product approvals, more detailed information than provided by the abstract can be obtained in the FOI summary. These summaries are easily accessed from CVM's website by simply inserting the NADA or ANADA number (another piece of information found on the package insert) for that product.

- The **Animal Safety** section provides an abstract of the results from the TAS studies that are required for FDA approval of the new animal drug. This information demonstrates the margin of safety for the drug. It also allows the reader to see what types of signs were observed in animals that received the drug at higher doses and for longer times than the intended dosage. It should help the practitioner decide whether or not to use the drug in animals that may be old, young, or have compromised organ function. If adverse signs in a treated animal are observed, the package insert provides information regarding whether or not similar signs were noted during the safety testing of this application.
- The **Storage Information** section describes the recommended storage conditions that are needed to maintain the potency of the drug within acceptable limits before the established expiration date. When applicable, this includes practical information for shipping, warehouse storage, and storage by the user. Any mandatory storage conditions are described (e.g., Store at controlled room temperature, 20–25°C (68–77°F)). When the drug is to be mixed with a diluent before use, this section describes the storage conditions for the diluted drug and also the time limitations for use of the diluted drug.
- **How the Product is Supplied** can include a description of the delivery device, the number of units per package, and the dosage strengths.
- The **NADA or ANADA Number and FDA Approval Statement:** The NADA or ANADA number can be used for searching the FDA/CVM website or for reporting product-specific adverse reactions. The presence of this section ensures the practitioner that they are using an approved new animal drug.

Classifying Prescription, Over-the-Counter and Veterinary Feed Directive Animal Drugs

FDA is responsible for determining the marketing status (Rx, OTC, or VFD) of animal drug products based on whether or not it is possible to prepare "adequate directions for use" under which a layperson can use the drugs safely and effectively. Prescription (Rx) products can be dispensed only by or upon the lawful written order of a licensed veterinarian.

Considerations include the potential toxicity or other harmful effects of the product, its method of administration, collateral measures necessary for its use (e.g., accurate diagnosis of a disease with reasonable certainty), and that the course of therapy can be followed for other potential safety risks or lack of success of the product.

The same drug substances can be marketed in a number of different dosage forms, intended for use by different routes of administration, and in different species of animals. Thus, these drug products may be appropriately labeled Rx in some cases and OTC in others. Veterinary prescription drugs must bear the legend: "Caution: Federal law restricts this drug to use by or on the order of a licensed veterinarian."

Before the passage of the ADAA, the FFDCA provided FDA only two options for regulating the distribution of animal drugs: OTC and Rx. The prescription legend invoked the application of State pharmacy laws, and the pharmacy laws in a significant number of States prohibited feed manufacturers from possessing and dispensing prescription animal drugs and medicated feed containing those drugs. Pharmacy laws in other States required the presence of a pharmacist at the feed manufacturing facility that uses prescription drugs in the manufacture of medicated feeds. As a practical matter, the application of State pharmacy laws to medicated feeds would burden State pharmacy boards and impose costs on animal feed manufacturers to such an extent that it would be impractical to make these critically needed new animal drugs available for animal therapy. For this reason, through the ADAA, Congress enacted legislation to create the VFD, providing a new class of restricted feed use drugs that may be distributed without invoking State pharmacy laws. Although statutory controls on the distribution and use of VFD drugs are similar to those for prescription animal drugs regulated under section 503(f) of the FFDCA (21 U.S.C. 353(f)), the VFD regulations are tailored to the unique circumstances relating to the distribution of animal feeds containing a VFD drug. Unlike prescription drugs, VFD drugs are not regulated by State pharmacy bodies. No extralabel use of a VFD drug is permitted and a veterinarian may issue a VFD only if a valid veterinarian–client–patient relationship exists, as defined in 21 CFR §530.11(b).

Abbreviated New Animal Drug Applications

Prior to GADPTRA, the FDA could approve abbreviated applications only for copies of animal drugs approved prior to 1962 and found to be effective under the DESI (drug efficacy study implementation) program. The intent of GADPTRA was to encourage competition and lower animal drug prices by allowing abbreviated applications for copies of previously approved drugs, without the generic drug sponsor duplicating the safety and efficacy studies that were required for the original NADA approval. GADPTRA permits an ANADA for an animal drug product that is the same as an animal drug product listed in the approved animal drug product list published by the Agency (listed new animal drug) with respect to conditions of use recommended in the product labeling, active ingredient(s), dosage form, strength, and route of administration.

An ANADA applicant may petition the Agency under Section 512(n)(3) of the FFDCA for permission to file an ANADA for a new animal drug product with certain defined changes from an approved pioneer product. The changes are limited to the following:

- a change of one active ingredient in an approved combination product;
- a change in dosage form;
- a change in dosage strength;
- a change in route of administration;
- a change in one active ingredient in a feed mixed combination.

A generic sponsor may file a suitability petition to request that the specific change in the pioneer product be allowed. The petition must follow the format and content described for a Citizen Petition (21 CFR §10.20) which is a public document filed with the FDA. The FDA response to the petition is also a public document. The Agency determines whether to deny or approve the petition.

ANADAs need to address all of the technical sections applicable to NADAs, but, in some cases, the information needed to fulfill these requirements is different. For example, target animal safety and effectiveness are evaluated through the demonstration of product bioequivalence between the pioneer and generic products. The focus of bioequivalence studies is to determine whether or not differences in product manufacturing and formulation will affect the rate and extent of drug absorption. The fundamental assumption of all bioequivalence testing is if the rate and extent of drug absorption are comparable, then the products will be medically indistinguishable and therefore interchangeable.

Bioequivalence studies (i.e., blood level, pharmacological end-point, and clinical end-point studies) and tissue residue depletion studies are conducted in accordance with GLP regulations (21 CFR Part 58). When absorption of the drug is sufficient to enable the quantification of drug concentrations in the blood (or other appropriate biological fluid or tissue) and if systemic absorption is relevant to drug action, a blood (or other biological fluid or tissue) level bioequivalence study should be conducted.

For certain generic drug products, the Agency may waive the requirement for demonstration of bioequivalence to the pioneer product. In general, the bioequivalence between solutions is considered to be self-evident for solutions with the same active and inactive ingredients in the same concentrations and with the same pH and physicochemical characteristics as the pioneer product. Categories of products that may be eligible for waivers include parenteral solutions intended for injection by the intravenous, subcutaneous, or intramuscular routes of administration, oral solutions or other solubilized forms, topically applied solutions intended to produce local therapeutic effects, and inhalant volatile anesthetic solutions.

When using serum or blood concentrations of drug in the evaluation of product bioequivalence, the principles underlying this assessment reflect a blending of pharmacokinetics and biostatistics. It is founded upon the principle that two formulations containing the identical active ingredient will exhibit the same safety and effectiveness if the two formulations exhibit the same rate and extent of absorption. In addition to its use in generic drug product applications, bioequivalence studies may be used to support the approval of proposed changes in the manufacturing of a generic version of an approved off-patent product or to cover the safety and/or effectiveness of a sponsor's own drug.

Blood level bioequivalence studies compare a test formulation to a reference formulation using parameters derived from the concentrations of the drug moiety and/or its metabolites (as a function of time) in the plasma, serum, or other appropriate biological fluid. This approach is applicable to dosage forms intended to deliver the active drug ingredient(s) to the site of action by way of the systemic circulation. Although usually conducted as a comparison of blood levels following single dose administration, a multiple dose study may be appropriate when there are concerns regarding poorly predictable drug accumulation. For details regarding the assessment of product bioequivalence, readers are referred to CVM Guidance #35 (*Bioequivalence Guidance*) as well as Chapter 3 of the present textbook.

Since veterinary generic drug products must contain all of the same indications, warnings, cautions, directions for use, etc. that are associated with the approved pioneer product (except as deemed appropriate on the basis of the Suitability Petition (21 CFR §512(n)(1)(F)), a bioequivalence study is generally needed for each species for which the pioneer product is approved (with the exception of "minor" species).

When the product in question is a generic product intended for use in a food-producing animal, sponsors are required to conduct both bioequivalence and tissue residue studies unless blood concentrations of the active drug can be measured out to the withdrawal time of the pioneer product. The requirement is based upon the conclusion that tissue residue depletion of generic products is not adequately addressed through blood level bioequivalence studies. Differences that may go undetected in a blood level study (and which would be without clinical significance) could impact the withdrawal time because the latter is based upon extremely low drug concentrations in the tissue (see section Human Food Safety). A tissue residue study should generally accompany clinical end-point and pharmacological end-point bioequivalence studies (21 USC 360b(n)(1)(A)(ii)).

The sponsor of the generic product application uses the existing tolerance, marker residue, target tissue, and analytical method (as contained within the pioneer product's approved NADA) to determine the withdrawal time for the generic product (FDA/CVM Guidance For Industry #35). Accordingly, generic sponsors need only monitor the depletion of the unlabelled marker residue in the target tissue to establish a withdrawal time for the generic product. However, for reasons explained above, there is a risk that the generic formulation will be associated with a withdrawal time that differs (longer or shorter) than that of the pioneer product. For this reason, the end-users of generic products should carefully read each product label to avoid the potential for incurring violative residues.

The Phased Review Process

For a sponsor to market a new animal drug in the United States, the sponsor must obtain an approval for their product through an NADA. Traditionally, a sponsor would generate all of the necessary data and information and file a complete NADA. Because of the complexity of an NADA, the likelihood of each component of the NADA being acceptable without working closely with CVM is small. This means that the sponsor has probably spent a significant amount of effort and resources developing an application that will need to be rehabilitated. This is not only inefficient but is also costly. For this reason CVM developed a Phased Review process where a sponsor could work with CVM to develop the components or technical sections of their NADA prior to filing their NADA. This higher level of interaction enables the sponsor to have each piece of their application reviewed under the investigational phase and receive feedback on the acceptability of their submission. Sponsors may submit study protocols, final study reports, and other information for review as they are produced.

Presubmission Conference

The Phased Review process starts with a meeting or series of meetings known as the presubmission conference. This meeting is very important for the success of the product development. During this meeting the sponsor provides scientific and technical information about their product and the proposed intended use(s) for their product. The sponsor outlines the safety and effectiveness issues that they perceive need to be addressed and how they intend to address them. CVM discusses these development plans with the sponsor leading to an understanding of the items that must be addressed for a successful development plan.

After the presubmission conference, a sponsor will work on each of the parts of the application or technical sections. The technical sections are target animal safety, effectiveness, human food safety, manufacturing chemistry, environmental impact, labeling, and all other information.

Outcomes of this conference will be documented in a memorandum of conference (MOC) as specified in 21 CFR 514.5.

Study Protocols

Submissions

Sponsors are not required to submit study protocols for review but do so voluntarily. If CVM concurs with the submitted protocol CVM is agreeing that the protocol design, execution plans, and data analyses are adequate to achieve the objectives of the study. If CVM does not concur, a letter will be given to the sponsor with as much detail as possible considering the quality and level of detail of the protocol submission to include a succinct assessment of the protocol. This response will also state whether the Agency agrees, disagrees, or lacks sufficient information to reach a decision.

Protocols should be well-written, clear, concise, and consistent across all sections so the investigator has a document outlining the study methodology and procedures. Data collection forms (e.g., case report forms, owner consent forms) should be included with the protocol and referenced in the section of the protocol where they are discussed. Relevant standard operating procedures (SOPs) for laboratory studies related to the collection of data should be appended to the protocol or an adequate description of the procedure should be incorporated into the protocol (for example, SOPs for describing parasite collection for anthelmintic studies or SOPs for culture and sensitivity microbiological procedures). If unsure, the sponsor should contact CVM to discuss which, if any, SOPs should be included with the protocol. Lack of detail in a study protocol may result in a refusal to review by CVM.

Protocol Development Meetings

Sponsors can request the scheduling of a protocol development meeting to discuss the specific details of a protocol. CVM strongly encourages a protocol development meeting for novel indication(s), novel products, and complex study designs. When requesting a protocol development meeting, sponsors should consider the timing of the meeting in relation to the submission of the protocol and any additional supportive information that may be needed.

Study Documentation and Submission

Using the protocol, a sponsor will conduct the study. Effectiveness studies are conducted in accordance with GCP Guidance, and safety studies are conducted in accordance with GLP regulations. When the study is completed and the final study report written, the sponsor will provide CVM with a study submission that contains the final study report and supporting documentation including the raw data for review. CVM will review the study for data integrity and for scientific merit. If the study is accepted, it will be used to support either a portion of or the complete technical section. When the entire technical section is complete, CVM will send the sponsor a technical section complete letter.

Administrative New Animal Drug Application

When a sponsor has received technical section complete letters for each of the required technical sections submitted to support approval of a new animal drug, the sponsor may file an Administrative NADA. The Administrative NADA contains a number for critical documents including the complete facsimile labeling, copies of all the technical section complete letters, and a signed FDA Form 356V. Upon receipt of an Administrative NADA, CVM will review and process the application to approval within 60 days.

Animal Drugs Intended for Minor Use/Minor Species

The Minor Use and Minor Species Animal Health Act of 2004 (the MUMS Act) was enacted to increase the availability of new animal drugs for minor species and for minor uses, while still ensuring appropriate safeguards for animal and human health. The MUMS Act provided for the establishment of the Office of Minor Use and Minor Species Animal Drug Development (OMUMS). OMUMS is responsible for overseeing the development and legal marketing of new animal drugs for minor uses (disease conditions that are rare) in major species (cattle, swine, chickens, turkeys, dogs, cats, and horses) and for minor species that fall under the category of "all other animals", including sheep, goats, game birds, emus, ranched deer, alpacas, llamas, deer, elk, rabbits, guinea pigs, pet birds, reptiles, ornamental and other fish, shellfish, wildlife, zoo animals, aquarium animals, and bees.

Because the markets are small and profit margins low for new animal drugs intended for minor uses in major species or for minor species, there are often insufficient economic incentives to motivate sponsors to develop the data necessary to support FDA approvals. In addition, some minor species populations are too small or their management systems too diverse to make it practical to conduct traditional studies to demonstrate safety and effectiveness. Consequently, manufacturers have not, in many cases, been willing to fund research to collect these data. Accordingly, very few new animal drugs intended for minor uses or for minor species have been approved and are legally marketed.

The limited availability of approved new animal drugs intended for minor uses or minor species, has limited the availability of options for treating these sick animals. In many cases, the choices are to leave a sick animal untreated or to treat the animal with an unapproved drug. Failure to treat sick animals appropriately may increase public health hazards. For example, the transmission of disease from animals to humans or the shedding of disease-producing organisms by untreated animals into the environment may increase health risks to humans as well as other animals. Treating an animal with an unapproved drug introduces questions of effectiveness and safety to the animal, to the environment, and to the public (e.g., human food safety).

The MUMS legislation modifies provisions of the FFDCA in three key ways, providing for:

- **Conditional Approval**: The sponsor of a veterinary drug can ask CVM for "conditional approval," which allows the sponsor to market the drug after proving the drug is safe and establishing a reasonable expectation of effectiveness, but before collecting all of the effectiveness data needed to support a full approval. The drug sponsor can keep the product on the market for up to 5 years, through annual reviews, while gathering the required effectiveness data.
- **Indexing:** The implementation of this regulation allows the FDA to add a minor species drug to an index of unapproved new animal drugs that may be legally marketed when the potential market for the drug is too small to support the costs of the drug approval process, even under a conditional approval. This provision is especially helpful to veterinarians treating zoo or endangered animals, and to owners of minor pet species such as ornamental fish or caged reptiles, birds, or mammals.
- **Designation**: This legislation provides incentives for approvals, such as grants to support safety and effectiveness testing. Sponsors must apply for designation prior to filing a new animal drug application for FDA approval. At the time that a designated drug gains approval or conditional approval, it is awarded 7 years of exclusive marketing rights. This means that FDA will not approve another application for the same drug in the same dosage form for the same intended use until after the 7 years have elapsed. This is 2–4 years longer than the protection provided from generic copying of nondesignated drugs. The MUMS marketing exclusivity also protects against approval of another pioneer (nongeneric) application for the same drug, in the same dosage form, for the same intended use.

Grants: The legislation also includes a provision that will allow Congress to appropriate funds for grants to defray the costs of safety and effectiveness testing for designated drugs.

Postapproval Monitoring of Animal Drugs

Postapproval monitoring of animal drugs is a very important function, necessary to ensure that the approved new animal drugs continue to be manufactured in accordance with their approval specifications and continue to perform as expected. In addition, CVM monitors the advertising and promotional material used by pharmaceutical sponsors to ensure that the product is represented in accordance with the conditions of its approved application. CVM uses Drug Experiencing Reports (DERs), Adverse Drug Experience Reports, and continued manufacturing facility inspections to conduct this monitoring.

Drug Experience Reports

Sponsors holding approved new animal drug applications are responsible for establishing and maintaining records concerning experience with the drug and Type A Medicated Articles containing the drug and for making reports of those experiences (21 CFR 514.80). Sponsors must file DERs within 30 days of the reporting period. After the initial approval, the first two reporting periods are at 6-month intervals, after which the reports are to be filed on an annual basis on the anniversary date of the approval.

The DER submission includes:

- unpublished reports of clinical or other animal experience, studies, investigations or tests conducted or reported to the applicant;
- experience, investigations, or studies involving the physical or chemical properties of the animal drug;

- copies of labeling that accompany the drug and copies of promotional labeling;
- advertising for drugs that are labeled for use by or on the order of a licensed veterinarian;
- quantities of the drug distributed to facilitate assessment of adverse effects;
- summary of reports of increased frequency of adverse drug experience (ADE)(See Section Adverse Drug Experience Reports);
- mix-ups with the new animal drug or its labeling;
- changes or deterioration of the new animal drug or failure of a batch to meet specifications;
- unexpected side effects, injury, toxicity, sensitivity reaction, or unexpected incidence or severity of side effects associated with chemical use irrespective of attribution to the new animal drug;
- failure of new animal drug to exhibit expected pharmacological action.

Adverse Drug Experience Reports

The primary purpose for maintaining the FDA/CVM ADE database is to provide an early warning or signaling system for adverse effects not detected during premarket testing of FDA-approved animal drugs and for monitoring the performance of drugs not approved for use in animals. The FDA/CVM ADE reporting system depends upon the detection of an adverse clinical event by veterinarians and animal owners, the attribution of the clinical event to the use of a particular drug ("suspect" drug), and the reporting of the ADE to the manufacturer of the suspected drug or directly to FDA. Data from these ADE reports are coded and entered into the computerized FDA/CVM ADE database. The reader should consult Chapter 58 for additional discussion of these topics.

It is important to remember certain caveats when using data from the FDA/CVM ADE database:

- For any given ADE report, there is no certainty that the suspected drug caused the adverse event. This is because veterinarians and animal owners are encouraged to report all suspected ADEs, not just those that are already known to be caused by the drug. The adverse event may have been related primarily to an underlying disease for which the drug was given, to other concomitant drugs, or may have occurred by chance at the same time the suspect drug was administered.
- Accumulated ADE reports should not be used to calculate incidence rates or estimates of drug risk. The Division of Surveillance is responsible for consolidation of all drug experience reports, necessary referrals and consultations, and preparation of the summary reports. The Divisions' ADE scoring system uses a modified Kramer scoring system (Bataller and Keller, 1999). In this system, each sign is separated from the other signs and scored according to previous experience with the drug, alternative etiological candidates (other causes), timing of the event, whether there was an overdose, whether the reaction continued or subsided with withdrawal of the drug, and whether a reaction recurred on reintroduction of a drug. Additional information on the criteria and responsibilities for the consolidation, screening, review, and evaluation of drug experience reports is further detailed in the CVM Program Policy and Procedures Manual section 1240.3522, Review and Evaluation of Drug Experience Reports (www.fda.gov/downloads/AnimalVeterinary/GuidanceComplianceEnforcement/PoliciesProceduresManual/ucm046832.pdf).)

Veterinarians and animal owners are encouraged to report adverse experiences and product failures to the government Agency that regulates the product in question. To access the FDA/CVM web site for information and forms that are needed to report adverse experience with veterinary drugs, the reader is referred to: www.fda.gov. Pretesting by the manufacturer and review of the data by the government does not guarantee absolute safety and effectiveness due to the inherent limitation imposed by testing the product on a limited population of animals. CVM encourages veterinarians and animal owners to contact the manufacturer of a suspect product. Withdrawal of an approved drug may be recommended if it is determined to be unsafe or ineffective.

The drug company marketing the drug product in question should be notified of the need to report an ADE for an FDA-approved animal drug. Drug company phone numbers can usually be obtained from product labeling. Technical services will ask a series of questions about the event, complete the FDA 1932 form, and forward the report to CVM. Alternatively, the report may be submitted directly to the FDA on Form 1932a.

Reports should preferably include a good medical history, all concomitant drugs the animal has been given, any recent surgical procedures, and as much in the way of clinical findings as is possible. Clinical findings may include veterinary exam, clinical chemistries, complete blood counts, urinalysis, fecal exams, radiographic results, and hemodynamic data such as blood pressure, any other pressure measurements in or around the heart, and neurological assessments.

"Veterinary Adverse Experience, Lack of Effectiveness or Product Defect Report" form FDA 1932a is a preaddressed, prepaid postage form that can be completed and dropped in the mail. This form may be obtained at: https://www.fda.gov/opacom/morechoices/fdaforms/FDA-1932a.pdf or by writing to:

ADE Reporting System
Center for Veterinary Medicine

US Food & Drug Administration
7500 Standish Place
Rockville, MD 20855-2773

The CVM can also be reached by phone at 1-888-FDA-VETS.

The Center may occasionally need more detailed information about an incident and the reporter may be called by a CVM staff veterinarian. The identities of all persons and animals is held in strict confidence by FDA and protected to the fullest extent of the law. The reporter's identity may be shared with the manufacturer or distributor unless requested otherwise. However, FDA will not disclose the reporter's identity to a request from the public, pursuant to the Freedom of Information Act. Information requested includes the reporter's name, address, phone number, and the brand name of the drug involved.

For information regarding CVM's surveillance program, the reader is referred to Chapter 58 of this textbook. Additional contact information includes:

- Pesticides: topically applied external parasiticides: US Environmental Protection Agency 800-858-PEST

International Harmonization

Historically, the FDA has been concerned with the safety and effectiveness of animal drugs produced or marketed within the USA. The FFDCA requires that exported pharmaceuticals meet or exceed the standards for approval in the USA *or* for the country to which they are being exported. It also requires that animal drugs marketed in interstate commerce in the USA be approved through the same process by the FDA, regardless of where they are manufactured.

In addition to the US FDA, other countries have independently developed regulations and regulatory agencies that review safety, effectiveness, and purity of drugs that are intended for marketing within their specific jurisdiction for use in humans and/or animals. Although, internationally, the regulations share the common goal of protection of public health, the specific requirements and methodologies used in the evaluations of these products may differ.

When pursuing a broad international market, products may undergo multiple complete and autonomous reviews by regulating agencies in different countries or regions, and differences in the regulatory requirements between these agencies can hinder the development of new drugs and drug products. Regulatory differences can also increase product development expenses, complicate international trade (both of products and of foods derived from animals consuming these products), and can lead to duplication of animal studies. Growing globalization, emergence and spread of new animal diseases, and the international nature of the scientific community make it important to share innovation in animal treatment across borders, while maintaining standards for safety, quality, and effectiveness.

Internationally, formation of the European Community (the EC), and later the European Union (the EU) served as an impetus for the development of a shared regional process for the approval of new animal drugs. This set a pattern for harmonizing separate and diverse regulations among member countries. In 1990, the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) was formed. This was followed by the International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products (VICH) in 1996. The VICH includes the USA, EU, and Japan as members, with the addition of Canada, New Zealand, Australia, and the Republic of South Africa as observers.

The objectives of the VICH are to:

- establish and monitor harmonized regulatory requirements for veterinary medicinal products in the VICH Regions, which meet high-quality, safety and efficacy standards, and minimize the use of test animals and costs of product development;
- provide a basis for wider international harmonization of registration requirements;
- monitor and maintain existing VICH guidelines, taking particular note of the ICH work program and, where necessary, update these VICH guidelines;
- ensure efficient processes for maintaining and monitoring consistent interpretation of data requirements following the implementation of VICH guidelines;
- by means of a constructive dialogue between regulatory authorities and industry, provide technical guidance enabling response to significant emerging global issues and science that impact on regulatory requirements within the VICH regions.

VICH Expert Working Groups, composed of scientific and technical experts representing each region, meet regularly to develop recommendations for more uniform standards for collection of preapproval and postapproval safety, purity, and effectiveness data. The goals of these Working Groups are to evaluate requirements of member agencies (within the context of current and emerging scientific knowledge), and to craft harmonized, science-based standards where ever possible. These standards are intended to maintain or enhance animal and public health and well being. Despite the challenges of reaching scientific and regulatory harmony, this process has led to a long list of approved and draft guidances, with more documents currently in development. These guidances are intended to allow the same studies to be used during the animal drug approval process of different regulatory agencies.

The FDA also participates in other international activities with a goal of protecting human and animal health in the global economy. During the early 1960s, the Food and Agriculture Organization (FAO) Conference and the World Health Organization (WHO) launched a joint effort to "protect the health of the consumers and ensure fair practices in the food trade". The primary product resulting from this program is the *Codex Alimentarius*, which literally means the "food code". This code represents a collection of food standards and guidance documents published jointly by the FAO and the WHO. Among these standards are maximum residual limits (MRLs) for veterinary drugs (MRLVD), as well as documents related to the use and control. The Codex Committee on Residues of Veterinary Drugs in Foods (CCRVDF) is specifically responsible for addressing the MRLVDF (www.codexalimentarius.org/.)

Concluding Thoughts

Working through the provisions of the FFDCA, the FDA/CVM safeguards the health and productivity of food-producing animals and companion animal species. These activities represent an interaction of science, statistics, veterinary practice, and law. These efforts are complicated by an ever changing scientific, political, and veterinary medical landscape. Nevertheless, as changes occur, regulators work diligently in an effort to accommodate new issues, concerns, and technologies.

Veterinary Pharmacy

Gigi Davidson and Mark G. Papich

Introduction

A pharmacist's responsibility for providing patients with high-quality pharmaceutical care extends beyond the human species. Although colleges of pharmacy and licensing boards have focused almost exclusively on human pharmacotherapy, society expects an equally competent quality of pharmaceutical care and products to be provided for nonhuman family members. Veterinarians are trained to provide quality care and products for animal patients, but few pharmacists receive training in pharmacy school about veterinary medicine. Pharmacists may be asked more frequently to dispense medications for animals in their day-to-day practice and they must familiarize themselves with veterinary pharmacotherapy and develop a clinically and legally sound algorithm for processing veterinary prescriptions. Pharmacists who dispense medications for animals have an obligation to become familiar with important species differences with respect to pharmacotherapy and susceptibility to drug adverse reactions (Table 56.1). Because this process is very slowly evolving in the pharmacy profession, veterinarians should be well versed in pharmacy issues related to veterinary medical therapy. Although several of these issues have been introduced or discussed in other chapters of this book, this chapter describes a variety of pharmacy-related topics of which all veterinarians should be aware.

Regulatory Discretion for Extralabel Use

Advances in medical knowledge occur at a much faster rate than do drug product approvals. Since it is impossible for a drug company to test marketed drugs in all species at all doses and for all indications, it is difficult for veterinarians to adhere to the strict limitations of approved drug labels. Passage of the Animal Drug Amendment in 1968 significantly restricted use of drugs in animals to use only in those species for which the product was labeled with strict adherence to the labeled indication, dose, route of administration, and duration of therapy. Any use of a human-labeled drug in animals, for example, was considered illegal under the 1968 Amendment. Pursuant to enactment of this legislation, veterinarians were forced to break the law most of the time when using drugs in their patients. Physicians, on the other hand, were still allowed to use any drug at any dose for any indication in human patients.

Realizing the impracticality of strict interpretation of this law for veterinarians, the Food and Drug Administration published compliance policy guidelines (CPGs) in 1993 to show veterinarians the boundaries for regulatory discretion by FDA inspectors. Four main CPGs provided the boundaries for drug use by veterinarians: Extralabel Drug Use, Human Label Drug Use, Use of Drugs in Food Producing Animals, and Compounding for Animals (see www.fda.gov for summaries of these CPGs); however, the CPG for Compounding for Animals was rescinded in May 2015 and replaced with Guidance For Industry #230, Use of Bulk Drug Substances in Compounding For Animals. Chapter 55 of this book provides a background on the drug approval process by regulatory authorities and a summary of the legal control of veterinary drugs.

Need for Legal Extralabel use — AMDUCA

Although these CPGs provided veterinarians with a higher comfort level for using drugs in animal patients, extralabel use of drugs in animals was still illegal. The law did not change; CPGs only informed veterinarians of occasions when FDA inspectors would exercise regulatory discretion with respect to interpreting and enforcing extralabel drug use. In 1993, veterinarians, increasingly frustrated by being forced to break the law, demanded the same legal right physicians had in treating their patients. On October 22, 1994, the Animal Medicinal Drug Use Clarification Act (AMDUCA) was passed allowing veterinarians to legally use drugs extralabel under certain circumstances. AMDUCA went into effect December 9, 1996. Concurrently, Congress passed the

Nonsteroidal antiinflammatory agents for humans (naproxen, ibuprofen)	Dogs, cats	Gastrointestinal ulceration and perforation, nephrotoxicity	Campbell and Chapman, 2000, p. 148, 192
Pennyroyal	Cats	Hepatotoxicity	Wismer, 2007
Permethrin	Cats	Neuromuscular and central nervous system toxicity	Campbell and Chapman, 2000, p. 238
Phenazopyridine	Cats	Hepatotoxicity and red blood cell oxidative injury	Harvey, 2006
Phosphate enemas	Cats	Profound hypocalcemia	Wismer, 2017
Pseudoephedrine	Dogs, cats	Cardiovascular and central nervous system stimulation	Plumlee, 2004a
Raw yeast dough	Dogs	Alcohol poisoning, gastrointestinal dilatation and volvulus	Warman, 2007
Salt	Dogs, cats	Hypernatremia, central nervous system toxicity	Campbell and Chapman, 2000, p. 42
Tobacco products	Dogs, cats	Muscle weakness, twitching, depression, tachycardia, shallow respiration, collapse, coma, and cardiac arrest	Plumlee, 2004b
Xylitol	Dogs, birds	Profound hypoglycemia and hepatocellular necrosis	Wismer, 2006

Animal Drug Availability Act, significantly expediting the process by which FDA approved products intended for use in animals. Passage of both laws was intended to significantly improve the ability of veterinarians to best treat nonfood-producing animal patients.

Animal Medicinal Drug Use Clarification Act

On October 22, 1996, the Animal Medicinal Drug Use Clarification Act of 1994 was enacted into law, allowing veterinarians to prescribe extralabel use of veterinary and human drugs for animals under specific circumstances and also codified compounding for animal patients provided the starting ingredients were FDA-approved drug products. The key extralabel provisions of the Animal Medicinal Drug Use Clarification Act are provided in Table 56.2. (A copy of the AMDUCA Extra Label Drug Use Guidelines Brochure is available in the February 15, 1998, issue of the Journal of the American Veterinary Medical Association (JAVMA) or may be obtained from the AVMA website: www.avma.org.) Some drugs are strictly prohibited from administration to food animals because a safe level of residue in food products cannot be identified (Table 56.3). Additional provisions

Table 56.2 Requirements for extralabel drug use (ELDU) in animals

- ELDU is permitted only by or under the supervision of a veterinarian.
- ELDU is allowed only for FDA-approved animal and human drugs.
- A valid veterinarian/client/patient relationship is a prerequisite for all ELDU.
- ELDU is for therapeutic purposes only (animal's health is suffering or threatened), not for production use.
- Rules apply to dosage for drugs and drugs administered in water. ELDU in feed is prohibited.
- ELDU is not permitted if it results in a violative food residue, or any residue that may present a risk to public health. FDA prohibition of a specific ELDU precludes such use (Table 56.3).

of the AMDUCA legislation require proper dispensing and labeling of prescribed drugs for animals (Tables 56.4 and 56.5).

Classification of Drugs

Drug

A chemical can be considered a drug if it meets one of the following criteria: (Chapter 5 of this book covers special considerations on pharmaceutics.)

1) It is an article recognized in one of the official compendia, i.e., the *United States Pharmacopoeia/National Formulary* or the official *Homeopathic Pharmacopoeia* of the United States or their supplements.
2) It is an article intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals.
3) It is an article other than food intended to affect the structure or any function of the body of man or other animals.
4) It is an article that is intended to be used as a component of an item falling into one of the three categories above.

Table 56.3 Drugs prohibited for extralabel use in food animals

- Chloramphenicol
- Clenbuterol
- Diethylstilbestrol (DES)
- Dimetridazole
- Ipronidazole
- Other Nitroimidazoles
- Furazolidone (except for approved topical use)
- Nitrofurazone (except for approved topical use)
- Sulfonamide drugs in lactating dairy cows (except approved use of sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine)
- Fluoroquinolones
- Glycopeptides (example: vancomycin)
- Phenylbutazone for female dairy cattle over 20 months of age

Table 56.4 Record requirements for drugs dispensed for animals

- Identify the animals, either as individuals or a group
- Animal species treated
- Numbers of animals treated
- Condition being treated
- The established name of the drug and active ingredient
- Dosage prescribed or used
- Duration of treatment
- Specified withdrawal, withholding, or discard time(s), if applicable, for meat, milk, eggs, or animal-derived food
- Keep records for 2 years
- FDA may have access to these records to estimate risk to public health

This definition does not differentiate between prescription drugs and nonprescription drugs, nor does it distinguish legal or lawful drugs from illicit ones. Because of this broad definition, *any substance that is used to treat an animal can be ultimately considered to be a drug and can be regulated and actionable as such.*

Legend ("Prescription") Drugs

Prescription drugs are limited to dispensing by or upon the order of a licensed prescriber ("prescription") because they are habit forming, are toxic, or have potential for harm. These drug labels contain the following warnings identifying them as legend drugs:

- *Veterinary Legend*: "Caution: Federal law restricts this drug to use by or on the order of a licensed veterinarian."
- *Human Legend:* "Rx only."

Legend (prescription) drugs *cannot* be dispensed without a prescription and may only be prescribed and dispensed within the confines of a valid veterinarian–client–patient relationship (VCPR) (Table 56.6). Because of the requirement of a valid VCPR, if a veterinarian has not examined the animal, he/she cannot prescribe legend

Table 56.5 Label requirements for drugs prescribed for animals

Name and address of the prescribing veterinarian
Established name of the drug
Any specified directions for use including the class/species or identification of the animal or herd, flock, pen, lot, or other group; the dosage frequency and route of administration; and the duration of therapy
Any cautionary statements
Your specified withdrawal, withholding, or discard time for meat, milk, eggs, or any other food

Table 56.6 A valid veterinarian–client–patient relationship (VCPR)

- The veterinarian has assumed the responsibility of making medical judgments regarding the health of the animal(s) and the need for medical treatment, and the client (owner or other caretaker) has agreed to follow the instructions of the veterinarian.
- There is sufficient knowledge of the animal(s) by the veterinarian to initiate at least a general or preliminary diagnosis of the medical condition of the animal(s). This means that the veterinarian has recently seen and is personally acquainted with the keeping and care of the animal(s) by virtue of an examination of the animal(s), and/or by medically appropriate and timely visits to the premises where the animal(s) are kept.
- The practicing veterinarian is readily available for follow-up in case of adverse reactions or failure of the regimen of therapy.

drugs for use in that animal. Likewise, a veterinarian cannot "fill a prescription" for an animal unless he/she has a valid VCPR with that animal. Veterinarians filling prescriptions for other veterinarians are considered to be practicing "pharmacy" and are subsequently subject to action by state pharmacy regulatory boards.

Over-The-Counter ("Nonprescription") Drugs

Over-the-counter (OTC) drugs are also considered "nonprescription" drugs. These are familiar to veterinarians and pet owners because they are available for human use in retail outlets such as pharmacies, markets, and grocery stores. Such OTC products can also be found for animals in the same retail outlets as for humans as well as in pet and feed stores. These drugs have been recognized by experts as safe and effective and bear extensive labeling that renders them safe for use by laypersons and are sold "over the counter," without a prescription.

All OTC products must be used *precisely* as labeled just as legend drugs. Use outside of these specifications constitutes extralabel use and the aforementioned guidelines should govern this use. Pharmacists must not make recommendations for use of human OTC drugs in animals unless so directed by a veterinarian. Veterinarians should avoid repackaging OTC medications for dispensing because reproducing the required labeling that is comprehensive enough for safe use by a layperson is difficult and dangerous.

VFD Drugs

A separate and unique category of drugs are those that fall under the Veterinary Feed Directive (VFD). A "VFD drug" is a drug intended for use in or on animal feed, which is limited to use under the professional supervision of a licensed veterinarian. A VFD drug is not a prescription drug, but is a written (nonverbal) statement issued by a licensed veterinarian in the course of the veterinarian's professional practice that authorizes the use of a VFD drug or combination VFD drug in or on an animal feed. Because there are new regulations that pertain to the VFD taking effect on January 1, 2017, this topic is discussed in more detail in Chapter 55 and 59 in the regulatory section of this book.

Controlled Substances

Controlled substances ("narcotics") are defined and monitored by the Drug Enforcement Authority (under jurisdiction of the Controlled Substances Act of 1970) and are divided into five schedules according to potential for abuse. An example of the schedules used for opiate drugs is provided in Chapter 13. Other controlled drugs are anesthetics and sedatives listed in Chapters 12 and 14. These drugs are strictly controlled by federal and state law and specific requirements for administering, dispensing, and prescribing are addressed in Section Prescribing Controlled Substances. Individual states are allowed to have more strict requirements than the federal (DEA) scheduling.

Compounded Drugs

Compounded drugs are mixtures of approved dosage forms or drugs formulated from bulk chemicals that are not approved by FDA for use as drugs in the United States. Veterinarians may compound items for their own use or write prescriptions for their patients for some of these active pharmaceutical ingredients to be used in preparing compounds by licensed pharmacists. These active pharmaceutical ingredients (e.g., potassium bromide, cisapride, diethylstilbestrol) are considered as drugs when used for therapeutic purposes and are recognized by FDA to be essential in the treatment of some companion, nonfood animals. As many of these drugs have been withdrawn from the market because of human safety hazards, the FDA has published a "negative" list (Drugs Withdrawn for Safety or Efficacy Reasons) for human compounding describing the drugs that are either prohibited for use in humans or are restricted to small dosages. Note that some of the drugs (e.g., cisapride and diethylstilbestrol) may still be compounded for nonfood animals such as companion animal pets but never for food animals or humans.

Current Status of Compounded Veterinary Drugs

Drug compounding has always been an important component of veterinary medicine. Historically, veterinarians have prepared concoctions, mixtures, and remedies for their patients because there were few approved formulations on the market for animals. Now, there are more available drugs for animals, and pharmaceutical science has provided for a better understanding of the factors contributing to poor drug bioavailability, instability, and physical incompatibility. Over the last several years, questions concerning the practice of compounding have been raised, particularly with respect to stability, purity, and strength when the original dosage form of the drug is altered. *(Note that the term "potency" used in some publications has been replaced by "strength" in this chapter because it is a more accurate term. Potency is used to describe the biological activity of a medication in a patient, and is not a measure of drug concentration.)*

Compounding is the alteration of the original drug dosage form for the purposes of ease of administration or because the original dosage form is unsuitable for the purpose intended. According to the United States Pharmacopeia (USP), compounding involves the preparation, mixing, assembling, packaging, and labeling of a drug or device in accordance with a licensed practitioner's prescription. The USP chapter on pharmacy compounding (Chapter <795>: Pharmaceutical Compounding—Nonsterile Preparations) states that "compounding is an integral part of pharmacy practice and is essential to the provision of health care" (USP-NF, 2015a).

Compounding does not include the preparation of a drug by reconstitution or mixing that is according to the manufacturer's instructions on an approved human or veterinary drug product.

The FDA issued a Compliance Policy Guide (CPG) for compounding drugs for use in animals in 2003 (FDA-CVM, 2003b). The 2003 version of the CPG provided guidance to FDA's staff with regard to the compounding of animal drugs by veterinarians and pharmacists for use in animals. However, in 2015 the agency withdrew Compliance Policy Guide Section 608.400 "Compounding of Drugs for Use in Animals" because it is no longer consistent with the FDA's current thinking on these issues. The FDA has prepared new guidance, referred to as "Guidance for Industry, or GFI #230". (Available at: http://www.fda.gov/AnimalVeterinary/NewsEvents/CVMUpdates/ucm446846.htm). At the time of this writing, the draft has not yet been finalized; therefore, it is not possible to indicate in this chapter how compounding will be regulated in the future. However, from the draft guidance, it is clear that the FDA intends to demonstrate regulatory discretion for use of bulk drug substances for compounding and intends to place stronger limits on the compounding from bulk sources. *Bulk drug substances* are defined as active ingredients used in the manufacture of finished dosage forms of the drug. Bulk drug substances are also referred to as *active pharmaceutical ingredients* (APIs). Current law does not permit compounding of animal drugs from bulk drug substances, but the FDA recognizes that there are limited circumstances when an animal drug compounded from bulk drug substances may be an appropriate treatment option. FDA's GFI #230 outlines specific conditions under which the agency generally does not intend to take action against state-licensed pharmacies, veterinarians, and facilities registered as outsourcing facilities when drugs are compounded for animals from bulk drug substances. It is anticipated that the new FDA Guidance on compounding from bulk drug substances will allow outsourcing facilities to prepare compounds from a limited list of bulk drug substances. Compounding from such a list by outsourcing facilities may be allowed in the absence of a prescription for an individual animal in instances such as drug shortages, or for when emergent use precludes waiting for a compound to be prepared pursuant to an individual prescription for an individual animal. *Outsourcing Facilities* are defined in The Drug Quality and Security Act, signed into law on November 27, 2013. This law created a new section 503B in the Food Drug and Cosmetic Act (FDCA). Under section 503B, a compounder can become an "outsourcing facility." The law defines an "outsourcing facility" as a facility at one geographic location or address that is engaged in the compounding of sterile drugs; has elected to register as an outsourcing facility; and complies with all of the requirements of section 503B. The FDA recognizes the importance of compounding in veterinary practice, but also must ensure that compounded drugs do not cause harm to the treated animals or their caregivers, that compounded preparations are bioavailable, effective, stable, and potent, and that compounded preparations do not cause drug residues in food animals. The proposed guidance mentioned above specifically refers to compounding from unapproved bulk drug substances.

FDA regulations permit the compounding of formulations from approved animal or human drugs under the current federal code: 21 CFR 530.13 (AMDUCA). The FDA is concerned that some compounding by veterinarians and pharmacists from bulk drug substances is performed to circumvent the usual drug approval process. Some activities performed under the guise of compounding (e.g., mass preparation of compounds that are wholesaled to veterinarians with no patient identified at the time of compounding, *dispensing* of compounds intended only for *administration* by the veterinarian in the office, or compounding less expensive copies of commercially available approved drugs) mimics exactly the manufacturing and distribution of what FDA defines as "new animal drugs." A court ruling by the 5th Circuit of Appeals (*Medical Center Pharmacy vs. Mukasey*, July 2008) reasserted that compounds prepared for animals outside of the provisions of AMUDCA fit the description of new animal drugs. New animal drugs must undergo the long and arduous FDA approval process to ensure the safety of the public health. Compounded products have not been subject to this scrutiny to determine the safety, efficacy, strength, purity, and stability required of drug manufacturers in order to receive FDA approval for marketing. Pharmacies are held to relevant USP Compounding standards by their state boards of pharmacy; however, under no circumstances can compounded products be manufactured or wholesaled. Licensed veterinary distributors who wholesale compounds from compounding pharmacies are in direct violation with licensure as granted by state licensing agencies (usually the Department of Revenue). Compounds must be prepared by pharmacists pursuant to a valid prescription order for an individual patient or prepared by outsourcing facilities for use in a veterinary practice (“office use”).

Potential Problems from Compounded Drugs

Because many drugs are not in a form that is ideal for the species being treated, either due to body size, taste preferences, or species-specific metabolic intolerances, commercially available drug products have been altered to make a more convenient and palatable oral dose form. However, when protective coatings on tablets or capsules are disrupted, and suspending or solubilizing vehicles are diluted or changed, the bioavailability and stability of the product may be compromised. (See Chapter 5 of this book for more detailed information on pharmaceutics.) In some instances, the only change is a slight alteration of pH. However, according to the USP (2015c), “improper pH ranks with exposure to elevated temperature as a factor most likely to cause a clinically significant loss of drug. A drug solution or suspension may be stable for days, weeks, or even years in its original formulation, but when mixed with another liquid that changes the pH, it degrades in minutes or days. It is possible that a pH change of only one unit could decrease drug stability by a factor of ten or greater.” Addition of a water-based solution to a product to make a liquid solution or suspension can hydrolyze some drugs (beta-lactams, esters). Some drugs undergo epimerization (steric rearrangement) when exposed to a pH range higher than what is optimum for the drug (for example, this occurs with tetracycline at a pH higher than 3). Other drugs are oxidized, catalyzed by high pH, which renders the drug inactive. Drugs most likely to be subject to oxidation are those with a hydroxyl group bonded to an aromatic ring structure. Oxidation may occur from exposure to light and oxygen during reformulation and mixing. Oxidation is catalyzed by high pH and usually leads to drug inactivation. Other factors contributing to instability and decrease in bioavailability may be through the addition of sugars and starches to an oral suspension. For example, it is well documented that the presence of sugar significantly decreases the stability of oral suspensions of atenolol and pyrimethamine, and the addition of methylcellulose to solutions of pyridostigmine will significantly decrease the oral bioavailability of pyridostigmine resulting in potential harm to the patient receiving these medications.

Table 56.7 Signs of drug instability of compounded formulations

Liquid dose forms
Color change (pink or amber)
Signs of microbial growth
Cloudiness, haze, flocculent, or film formation
Separation of phases (e.g., oil and water, emulsion)
Precipitation, clumping, crystal formation
Droplets or fog forming on inside of container
Gas or odor release
Swelling of container

Solid dose forms
Odor (sulfur or vinegar odor)
Excessive powder or crumbling
Cracks or chips in tablets
Swelling of tablets or capsules
Sticking together of capsules or tablets
Tackiness of the covering of tablets or capsules

Veterinarians and pharmacists are obligated to be cognizant of the potential for interactions and interference with stability (Table 56.7). Oxidation is often visible through a color change (color change to pink or amber, for example). Loss of solubility may be observed through precipitation. Some drugs are prone to hydrolysis from moisture. A rule-of-thumb for veterinarians is that if a drug is packaged in blister packs or moisture-proof barrier, it is probably subject to loss of stability and strength if mixed with aqueous vehicles. If compounded formulations of solid dose forms show cracking or “caking,” or swelling, the formulation has probably accumulated moisture and may have lost strength over time. Another rule-of-thumb is that if the original packaging of a drug is in a light-resistant or amber container it is probably prone to inactivation by light. Vitamins, cardiovascular drugs, and phenothiazines are labile to oxidation from light during compounding. Also, as a general rule, if an antibiotic is available in a powder that must be reconstituted in a vial or oral dispensing bottle prior to administration, it is probably unstable for long periods of time and should also not be mixed with other drugs.

Examples of Potential Problems

There are published studies in which drugs for veterinary patients have been tested for strength over time or stability under the conditions used during compounding. In a commercial formulation, the inactive ingredients and excipients are added to drug formulations to ensure the stability of the drug; provide an optimum chemical environment, pH; or increase the ease of packaging or handling. However, adding other chemicals, flavorings, or vehicles, or interfering with protective coatings of tablets may affect the stability of the drug, decreasing strength, oral absorption, and efficacy. There are published formulas in compounding journals, and texts, but few of these formulations have been tested for safety, efficacy, bioavailability, stability, strength, and purity for use in the target species. Veterinarians are responsible for the risk to an animal, or person handling the medication, when they prescribe compounded preparations. Pharmacists and veterinarians preparing compounds for animal patients are obligated to be in compliance with USP compounding standards. They have an obligation to request evidence from compounding pharmacists about the stability and strength of formulations prepared for their patients. When veterinarians compound formulations in their own practices, they should be cognizant of the potential interactions and alterations that may compromise the stability and strength of the active ingredient and should not attempt compounding without proper training, equipment, and quality assurance techniques

There are published examples in which drug stability and efficacy have been compromised through compounding. For example, when omeprazole was compounded for oral use in horses, it was not as effective for treating gastric ulcers as the commercial formulation registered for horses (GastroGard) (Nieto et al., 2002). Systemic bioavailability and strength of the compounded formulation was not as high as for the proprietary product. Omeprazole is known for its instability unless administered in the original formulation intended for horses or people. On the other hand, when the FDA-approved equine paste (GastroGard ®) was compounded in oil for dogs and cats, it retained the original strength for 6 months (unpublished data from laboratory of MG Papich).

Fluoroquinolone antibiotics are frequently modified for administration to exotic animals and horses. The compatibility of enrofloxacin and orbifloxacin with flavorings, vehicles, and other ingredients has been evaluated. With few exceptions, this class of drugs is compatible with most mixtures and remarkably stable. Enrofloxacin retained strength when the FDA-approved product was mixed with various vehicles and flavorings for exotic animals (Petritz et al., 2013). A notable exception is the chelation of enrofloxacin with iron and aluminum-containing products (e.g., antacids, sucralfate, mineral supplements, iron-containing molasses), in which a significant portion of the medication may become unavailable for absorption. It has also been observed that certain mixtures and flavorings may be incompatible with fluoroquinolones if they contain metal ions that are known to cause chelation. For example, when crushed orbifloxacin tablets were mixed with a vitamin and mineral supplement (Lixotinic) that is sometimes used as a flavored vehicle for oral administration of drugs, the strength of orbifloxacin was decreased from its original concentration by 50%. (Lixotinic contains 2.5 mg/ml iron.) Other flavorings and vehicles (for example, corn syrup, regular molasses, fish sauce, and Syrpalta) had no effect.

Antifungal drugs are subject to instability if not maintained at an optimum pH and formulation conditions. Itraconazole is frequently compounded from the bulk chemical or the proprietary capsules. However, itraconazole must be complexed onto cyclodextran in order to be orally bioavailable, and as bulk chemical preparations of itraconazole are not complexed in this fashion, they have not been found to be orally bioavailable in animal patients (Mawby et al., 2014). Itraconazole may also adsorb to plastic and glassware during compounding, decreasing the predicted strength of the finished preparation.

When doxycycline hyclate was compounded from FDA-approved tablets in an aqueous vehicle, it retained strength for only 7 days. After 7 days it degraded and showed a change in color and consistency (Papich et al., 2013).

Aminoglycoside antibiotics (gentamicin, tobramycin, kanamycin) are inactivated when admixed with other antibiotics, particularly beta-lactams. This interaction is greatest from carbenicillin, followed by ticarcillin, penicillin G, and ampicillin. Loss of strength by as much as 50% can occur within 4 to 6 hours. This interaction is a potential problem when antibiotic mixtures are prepared in a vial or fluid administration set and dispensed to be used several hours later. This interaction does not occur intravascularly at therapeutic concentrations in the patient because the drugs are diluted out in plasma and body fluids (Bowman et al., 1986), but visual precipitation of these agents in IV administration sets is commonly reported when they are mixed.

Drugs formulated as acids – such as the hydrochloride form of basic drugs – are formulated to maintain their solubility in aqueous solutions. However, when these formulations are mixed with other drugs that are more basic, or added to basic vehicles, drug precipitation may occur.

Several drugs are not soluble in aqueous vehicles. Therefore they are dissolved in organic solvents (propylene or ethylene glycol, for example) or alcohols. These are notoriously unpalatable to some animals, particularly cats. However, if these formulations are diluted in aqueous fluids, precipitation may occur. When these are stored at home by the pet owner, precipitation of the drug to the bottom of the container results in dilute oral dosing when the container is sampled from the top, and highly concentrated formulation when the container is sampled from the bottom (assuming that the precipitate at the bottom can be resuspended). This also may be observed when mixing some drugs in aqueous fluids. For example, if diazepam solution (which contains propylene glycol and alcohols) is diluted in saline solution or Lactated Ringer's solution, precipitation occurs.

Compounded Transdermal Medications for Pets

Because of convenience, ease of administration, and therapeutic success with some transdermal drugs (antiparasitic agents and fentanyl), there is considerable interest in formulating a wide range of other drugs for use by this route. Historically, transdermally administered drugs were formulated for single-dose delivery in a liquid preparation, or for continuous delivery out of a drug-releasing matrix or "patch." A compounding pharmacist (Marty Jones, PharmD) discovered a penetration-enhancing drug vehicle in the 1990s, and application of this delivery system to drugs used in animals rapidly caught on. A quick Internet search of "compounding pharmacy + transdermal" will reveal over 11,000 advertisements from compounding pharmacies who provide drugs in transdermal delivery gels. Noninvasive, nonstressful, palatable drug delivery is an attractive option for many veterinary patients, especially cats. Consequently, many veterinarians are eager to try this dosage form on fractious or fragile patients who should not be (or do not want to be) stressed during medication. While transdermal drug delivery is appealing, there is only one drug (methimazole) that was shown to produce therapeutic benefits when compounded and administered via the transdermal route in cats. The skin is a formidable barrier to drug penetration, and drug absorption into systemic circulation is difficult (Riviere and Papich, 2001)(see Chapter 47 of this book). In order to facilitate drug transport across skin, drugs need to be small in molecular weight and placed in a biphasic vehicle that can propel the drug across the various lipophilic and hydrophilic layers of the skin. Passage of the drug across the skin relies on the thickness of the skin, the partition coefficient of the drug, the diffusion coefficient of the skin, and the concentration of drug in solution. The partition coefficient, the diffusion coefficient, and the thickness of the skin are not alterable; therefore, transdermally applied drugs must be placed in high concentrations in vehicles that accommodate the various coefficients of diffusion. There are few drugs that can meet these criteria to be successfully absorbed by this route.

One commonly used penetration enhancer is pleuronic lecithin organogel (PLO), which is lecithin (derived from eggs or soybeans) mixed with isopropyl palmitate and a poloxamer (Pluronic). The ingredients in PLO act as surfactants, emulsifiers, and solubilizing agents to escort drug across the skin into systemic vasculature. There are many other penetration-enhancing vehicles (e.g., Lipoderm, Van Penn) utilized to compound transdermal preparations, but at the time of writing, there are no FDA-approved formulations that utilize these penetration-enhancing vehicles to deliver systemic drugs. Most FDA-approved transdermal drugs for people are available as patch delivery systems (e.g., patches containing fentanyl, lidocaine, or buprenorphine), or are single-dose applications of parasiticides for animals. Compounded transdermal preparations are formulated in high concentrations so that a therapeutic dose may be delivered in 0.1–0.2 ml, which is applied to a hairless area and rubbed in until no residue remains on the skin surface. Because the drug must be in solution in order to penetrate skin, many drugs are logically precluded from transdermal administration because they are not soluble in concentrations high enough to deliver a dose in 0.1–0.2 ml (e.g., any drug dosed at 10 mg/kg requires a transdermal concentration of at least 500 mg/ml to deliver a 0.1-ml dose to a 5-kg cat). The majority of drugs are not soluble at these high concentrations.

Single-dose pharmacokinetic studies for transdermally administered drugs have demonstrated that absorption was incomplete, nonexistent, or highly inconsistent among study cats, and that after single doses, bioavailability was low compared to a single oral dose. There have been an even smaller number of chronic dosing safety and efficacy studies for transdermally administered drugs, and few of those demonstrated positive evidence of efficacy. Transdermally administered drugs examined so far have included methimazole, amlodipine, glipizide, dexamethasone, buspirone, amitriptyline, metoclopramide, atenolol, fentanyl, morphine, fluoxetine, ondansetron, theophylline, and diltiazem. Methimazole was not absorbed well according to a pharmacokinetic study (Hoffman et al., 2002; Trepanier, 2002), but produced clinical efficacy with repeated transdermal application in other studies (Hoffman et al., 2001). It is suspected that efficacy from repeated doses of transdermal methimazole is attributed to the cat rubbing their paw on the ear, then licking the medication from the paw producing oral absorption. Transdermal amlodipine produced a change in blood pressure in a small study in hypertensive cats (Helms, 2007), but it is known that blood pressure response from amlodipine in cats can be highly variable. Absorption of atenolol from a transdermal preparation in cats was low and inconsistent and did not produce therapeutic blood levels of atenolol after a week of chronic dosing at an equivalent oral dose (MacGregor et al., 2008). The remaining drugs were examined as single-dose pharmacokinetic studies and showed poor bioavailability as compared to oral dosing and a high degree of intrasubject variation in drug absorption.

A major concern for use of transdermally administered drugs, for which there is no safety, efficacy, or strength evidence, is the risk of poor absorption or decreased stability of the formulated drug. For example, unstable or poorly absorbed transdermal antibiotics may result in therapeutic failure or increase the risk of antimicrobial drug resistance. Misinterpretation of single-dose pharmacokinetic studies might lead prescribers to increase transdermally administered drug doses, leading to accumulation of drug and severe toxicity. For example, the transdermal bioavailability of amitriptyline was 10% compared to oral dosing in a single dose pharmacokinetic study. Several veterinarians erroneously interpreted these results to mean that transdermal amitriptyline should effectively be administered at 10 times the oral dose. Other poor candidates for transdermal administration include drugs that are known to be contact irritants or phototoxins. In addition to bioavailability rationale, veterinarians evaluating drugs for transdermal application should also consider the local damage caused by these drugs (e.g. clopidogrel, doxycycline, fluoxetine, enrofloxacin) when applied to thin, hairless skin (e.g. pinnae). Obviously, there also is considerable risk for absorption by the human caregiver. Drugs toxic to humans (e.g., chloramphenicol, diethylstilbestrol, carprofen, digoxin anticancer agents) are extremely poor candidates for transdermal drug administration. Similarly, caregiver health and lifestyle must also be considered when prescribing transdermal drugs for pets. For example, a hypothyroid owner is a poor candidate to administer transdermal methimazole to her hyperthyroid cat, and a long-distance truck driver subject to periodic drug testing is a poor candidate for administration of transdermal opiates to his pet in pain.

Compounding Guidelines for Veterinarians and Veterinary Pharmacists

The future FDA-CVM guidance on compounding (GFI #230) will define the extent of compounding from bulk substances that will be allowed after this guidance if finalized. In the meantime, there are restrictions that apply to compounding in general, and each state may have more restrictive requirements than federal law. In the meantime, compounded therapies should be prepared from a commercially available formulation, if a suitable approved product exists, and compounding pharmacies should follow existing standards and guidelines.

The United States Pharmacopeia (USP), a national standard-setting organization for pharmaceuticals, lists specific standards for pharmaceutical compounding in Chapters <795> Pharmaceutical Compounding—Non-Sterile Preparations, and <797> Pharmaceutical Compounding—Sterile Preparations, (USP-NF, 2015a). One important standard for compounded preparations is that the final strength of the finished preparation is not less than 90.0% and not more than 110% of the theoretically calculated and labeled quantity of active ingredient per unit weight or volume. There are also guidelines available for stability considerations in the chapter on Observing Products for Evidence of Instability (Chapter <1191>) (USP-NF, 2015b). Generally, the beyond-use dating (BUD) for a nonaqueous solid compounded dosage form should not be later than the time remaining until the expiration date of the shortest-dated ingredient or 6 months, which ever is shorter. For water-containing oral formulations the beyond-use date is not later than 14 days stored at controlled cold temperatures, and for nonaqueous liquid formulations USP Chapter <795> allows for the beyond-use date to be no later than 180 days. For water-containing topical formulations, the beyond use date is 30 days at controlled room temperature. These limits may be exceeded when there is supporting valid scientific data that applies to the specific compounded formulation.

The Society of Veterinary Hospital Pharmacists, an organization of academic veterinary teaching hospital pharmacists, has published a position statement on Compounding For Animal Patients that may be consulted by pharmacists or veterinarians for further guidance (http://svhp.org).

Finally, veterinarians should seek the services of a Pharmacy Compounding Accreditation Board (PCAB) accredited pharmacy when prescribing compounds. Formed in 2004 by eight national pharmacy organizations, the nonprofit PCAB runs a voluntary accreditation program to ensure quality standards for compounding pharmacies. Once a pharmacy applies for PCAB accreditation, they must undergo a rigorous standards evaluation that is then validated by multiple site visits and inspections by PCAB surveyors. If a pharmacy meets the incredibly rigorous accreditation standards, a veterinarian can be assured that the pharmacy is legally and ethically impeccable and that its compounds are of the highest possible quality. At the time of this writing, PCAB has accredited more than 300 pharmacies in the United States. PCAB maintains an interactive map of accredited pharmacies in each state, list of accredited compounding pharmacies on their website, or veterinarians can contact PCAB's executive director to find an accredited pharmacy in their state. Further information regarding PCAB can be reached at: http://www.achc.org/compounding-pharmacy.html.

Unapproved Drugs Available by Importation

There was a mechanism in the past whereby a veterinarian could obtain an unapproved drug or dosage form through importation from other countries by filing a Medically Necessary Personal Veterinary Import form with FDA-CVM. This mechanism is no longer sanctioned by the FDA-CVM.

Prescribing Controlled Substances

A veterinarian who administers, dispenses, or prescribes controlled substances in the course of his practice *MUST* register with the Drug Enforcement Authority (DEA). This requires submission of an application, which may be obtained from the DEA. Practitioners must have a separate registration for every practice site employed. State regulations also must be followed and practitioners must contact their state authorities to determine the requirements. Some states have stricter regulations that the Federal drug schedules. Veterinarians can find out more about the DEA drug schedules and handling of controlled substances in their practice by viewing the DEA web site (see: http://www.deadiversion.usdoj.gov/schedules/).

Prescribing controlled substances requires submission of appropriate forms and maintaining records for controlled substances. Documentation must be made in the patient's medical record of all controlled substances administered, and such records must be stored in a readily retrievable fashion for 3 years. Appropriate entries must be made for waste or disposal of unused portions of controlled substance and witness is required for disposal. Records must be kept of all controlled substances dispensed, and such records must be stored in a readily retrievable fashion for 3 years. While the law does not specifically require a dispensing record separate from the medical record, a separate recordkeeping system provides more readily retrievable dispensing records than does the patient's medical record. A separate dispensing log does *NOT* replace the need to document dispensing of drugs in the medical record because these drugs are still restricted to the order of a licensed practitioner. It is also recommended that Schedule II dispensing records be maintained separately from other records.

Prescribing Records

Practitioners are not required to keep records of prescriptions written for controlled substances, but it is in the best interest of the veterinarian to make a note of such prescriptions in the patient's medical record to provide for a complete patient medical profile.

Inventory Records

All DEA 222 order forms for Schedule II orders as well as other commercial invoices accompanying controlled drugs must be signed and dated, and items must be counted, noted, and stored in a readily retrievable file for 3 years. Schedule II records must be stored separately from Schedule III-V records.

A complete and accurate inventory of all stocks of all controlled substances must be taken every 2 years on the anniversary of the practitioner's initial DEA registration. The written inventory should contain the following information:

- the name, address, and DEA registration number of the registrant;
- the date and time the inventory is taken;
- the signature of the person taking inventory;
- an indication that the inventory is maintained for at least 2 years at the location appearing on the registration;
- an indication that inventory and other records of Schedule II drugs are maintained separately from other drugs.

Storage and Security of Controlled Substances

Controlled substances "must be stored in a securely locked, substantially constructed cabinet." If there is loss or theft, upon discovery of loss of theft of controlled substances, the registrant must immediately notify the region office of the DEA and then must complete DEA form 106 describing the loss. If a theft is verified, the local police department must also be notified.

Dispensing Medications Intended to Go Home with a Patient

Many state and federal legal requirements exist for the act of dispensing a drug to go home with a patient. Any prescription medications that leave a practice to go home with a patient must be labeled with the information indicated in Table 56.8.

Any medications that leave a practice to go home with a patient should be packaged in a child-resistant container as described by the Poison Prevention Packaging Act.

Table 56.8 Drug dispensing labeling requirements

- Name, address, and phone number of the dispensing facility
- Name of client
- Animal identification (name and species)
- Date dispensed
- Full directions for use
- Name, strength, and quantity of drug dispensed
- Name of prescribing veterinarian
- For controlled substances, the label must also contain the message "Caution: Federal law prohibits transfer of this drug to any person other than the patient for whom it was prescribed."

Table 56.9 Requirements for writing a prescription for noncontrolled substances

The elements listed below are required by law to be included on the written prescription document:

- Printed or stamped name, address, and telephone number of the licensed practitioner
- Legal signature of the licensed practitioner
- Name and strength of drug
- Directions for use
- Full name and address of the client
- Animal identification (name and/or species)
- Cautionary statements including, if applicable, withdrawal times for food animals
- Number of refills, if any

Table 56.10 Requirements for writing a prescription for controlled substances

The elements listed below are required by law to be included on the written prescription document:

- Printed or stamped name, address, and telephone number of the licensed practitioner
- DEA registration number of the licensed practitioner
- Legal signature of the licensed practitioner followed by printed name of the practitioner
- Name and strength of drug
- Directions for use
- Full name and address of client
- Animal identification (name and/or species)
- Cautionary statements including, if applicable, withdrawal times for food animals

No refills are allowed on Schedule II prescriptions and refills are limited to 5 times or 6 months (whichever comes first) on prescriptions for drugs in Schedules III–V.

The Act applies only to drug dispensed for human use, but should be followed to prevent unintentional human poisonings from animal drugs. Medications dispensed in nonchild-resistant containers should be adequately labeled with auxiliary labels indicating "Caution: Package not child resistant" and "Keep out of reach of children." Other auxiliary labels detailing important information such as "shake well," "refrigerate," "not for injection," etc. should also be affixed to the container.

Table 56.11 Officially recognized Latin abbreviations used in prescription writing

a.c.	before meals	ml	milliliter
a.d.	right ear	o.d.	right eye
a.s.	left ear	o.s.	left eye
a.u.	both ears	o.u.	both eyes
amp	ampoule	p.c.	after meals
b.i.d.	twice daily	p.o.	by mouth
cc	cubic centimeter	p.r.n.	as needed
c	with	q.	every
cap	capsule	q4h	every 4 hours, etc.
disp	dispense	q.i.d.	four times daily
g or gm	gram	q.s.	a sufficient quantity
gtt(s)	drop(s)	Sig.	directions to patient
h	hour	SQ	subcutaneously
h.s.	at bedtime	stat	immediately
IM	intramuscularly	susp	suspension
IP	intraperitoneally	tab	tablet
IV	intravenous	TBSP	tablespoonful (15 ml)
kg	kilogram	t.i.d.	three times daily
lb	pound	tsp	teaspoonful (5 ml)
m^2	meter squared	Ut. dict	as directed
mg	milligram		

Do not use q.d., q.o.d., and s.i.d. because they are confused with other abbreviations; s.i.d. is unknown to health professionals outside of veterinary medicine. If in doubt about an abbreviation, write out the directions in plain English. Also, avoid using abbreviations such as b.i.d., t.i.d., q.i.d., as they are confusing to clients. Abbreviations such as q12h, q8h and q6h are much clearer.

Prescription Writing

A prescription is a written order or other order, which is promptly reduced to writing for a controlled substance or for a preparation, combination, or mixture thereof, issued by a practitioner who is licensed in his state to administer and prescribe drugs in the course of his professional practice. A prescription does not include an order entered in a chart or other medical record for drugs administered. Always store blank prescription pads in a secure place with access limited to minimal personnel. The elements required in a valid prescription are provide in Tables 56.9 and 56.10. When writing a prescription, abbreviations are allowed. Some commonly accepted and recognized abbreviations are listed in Table 56.11. When in doubt about an abbreviation, *spell it out.*

Medication Control Programs in Performance Animals

Cynthia A. Cole

Regulation of Drug and Medication Use in Performance Animals

Horses, dogs, and other species frequently compete in athletic events in which the use of drugs and medications are controlled. The programs are often referred to as doping control: doping being the colloquial term for the illegitimate use of drugs to alter athletic performance in animals and man. The goals of medication control programs generally fall into three categories: (i) assure a fair and level playing field for the competitors, (ii) protect the health and welfare of the animal and human participants, and (iii) safeguard the public interest, whenever parimutuel wagering is involved. A major challenge in these programs is to control doping, but not to interfere with the legitimate use of veterinary medications. In addition, what is a medication in one setting could be seen as doping in another. For example, medicating a horse during the training phase to assist in healing from an injury is entirely legitimate, but administration of those same medications on race day, would likely be construed as doping (i.e., trying to make a sore horse sound enough to compete). Rarely is the differentiation between doping and appropriate veterinary care so obvious, however. For example, as laboratory methodologies have improved, it is now possible to detect some drugs days, weeks, or in some cases a month or more after they have been administered. This has led to the pivotal question of what is appropriate medical treatment of animal athletes. Treating a horse or dog during training is generally deemed acceptable, but residues of those medications can be detected long after they cease to have any demonstrable pharmacological activity. The difficulty in these situations is differentiating between a pharmacologically insignificant residue and one that may be associated with a pharmacological effect, even if that effect is small.

Overview of Regulatory Agencies and Stakeholder Organizations

It is important for veterinarians who treat animals that compete in events governed by medication control programs to understand that the regulatory environment is a dynamic one. What is permitted today in a program may be forbidden tomorrow. In addition, the sensitivity of the testing methods used to regulate compliance with medication rules continues to increase. As a result, the times required to discontinue the administration of medications prior to a competition in order to avoid positive tests, often referred to as withdrawal times, are also increasing. Veterinarians need to know what regulatory agency has authority over the events in which their clients are competing, so they can keep abreast of changes in medication rules and help their clients comply with them.

Racing Animals

Although there has been some discussion among industry stakeholders of the need for federal regulation, currently, medication rules for racing animals in the United States are determined by the individual states. States may have a Racing Commission, a Division of Parimutuel Wagering, or some other state agency that is given the authority and responsibility of regulating racing animals, horses and/or Greyhounds. It is the parimutuel wagering component of racing that has resulted in government oversight of these animal sports. Rules can vary significantly from state to state, so it is important to review the regulations in each state.

Although each state sets its own rules and regulations, there are several organizations that work to encourage harmonization of the programs. This is important because over a course of several weeks or months many

Companion Website: www.wiley.com/go/riviere/pharmacology

horses may routinely race in several different states. The Association of Racing Commissioner's International (ARCI) consists primarily of racing regulatory officials from the USA, Canada, and Caribbean (www.arci.com). It has no direct rule making authority, but the organization has developed model rules and penalty guidelines, which many states use as a framework for their regulations.

Another industry association is the Racing Medication and Testing Consortium (RMTC) the stated goals of which are to: develop and promote uniform rules, policies, and testing standards at the national level; coordinate research and educational programs that seek to ensure the integrity of racing and the health and welfare of racehorses and participants; and protect the interests of the racing public (http://rmtcnet.com). The organization consists of racing industry stakeholders and, similar to ARCI, it has no regulatory authority, but it does wield a great deal of influence. It has funded a significant amount of research related to drug and medication issues in racing horses and has developed a comprehensive Laboratory Code of Standards, as well as operating an External Quality Assurance Program. It also has developed withdrawal guidelines for many therapeutic substances and has worked closely with ARCI on model rules and a classification guideline for foreign substances.

In 1993 the International Federation of Horseracing Authorities (IFA), which has member countries around the world, was formed to: coordinate and harmonize the rules of the member countries regarding breeding, racing, and wagering, ensure the quality and fairness of racing, protect the welfare of horses, jockeys, and the people attending horseraces, and keep horseracing up to date with technical, social, and economic changes (www.horseracingintfed.com). Its interests are broader in scope than either the RMTC or ARCI, which are more North American centric, but its influence in the North America is also less than those other organizations.

Nonracing Drug and Medication Rules

In the United States the largest governing body for drug and medication rules covering nonracing horses is the United States Equestrian Federation (USEF). A private, nongovernmental organization, the USEF regulates the vast majority of equine nonracing athletic events in the USA, including disciples recognized by the Federation Equestre International (FEI), which represents the most elite levels of equestrian competitions worldwide. The USEF has two rules under which the various breed groups and riding discipline organizations can choose to hold their competitions. Most breeds and disciplines that compete under USEF rules are subject to the Therapeutic Substance Provisions, which allows certain therapeutic medications to be present in clinically significant concentrations, while banning the presence of others outright. The Prohibited Substance Provisions rule, under which all FEI and Endurance competitions are conducted, classifies drugs as either controlled medications or banned substances. In this rule even controlled medications can only be present in nonpharmacologically significant concentrations, and therefore it is a much stricter rule than the Therapeutic Substance Provisions rule. The exact rules and regulations are updated frequently and details on both rules and advice on how to comply with them can be found on the USEF website (https://www.usef.org/_IFrames/Drugs/Default.aspx).

The Drug Testing Process

In order to ensure compliance to drug and medication rules, biological samples are collected from animals participating in competitions either during or immediately after the event. There are a number of private and state run forensic drug testing laboratories that specialize in analyzing these samples for the presence of nonpermitted medications and overages of permitted, but controlled, medications. The testing process aims to separate and identify nonendogenous components or drugs in biological matrixes. The process can be separated into four steps: (i) sample collection, (ii) extraction, (iii) separation, and (iv) detection and identification.

Sample Type

Most commonly, urine and/or blood samples are collected and analyzed for the presence of nonpermitted substances and overages of permitted medications. Traditionally, urine has been used primarily for regulating nonpermitted substances, whereas blood samples were used to control permitted medications through adoption of regulatory limits or thresholds, but this approach is changing.

The selection of urine as the analytical matrix of choice is often made because it can be collected noninvasively with relative ease, particularly in horses. The large volumes typically voided in horses are also an advantage. In dogs, collection is a bit more difficult and volumes are often limited, but it is still the most common fluid collected in drug testing programs. Because many, if not most, drugs are eliminated in the urine and the kidney concentrates the urine, drugs can generally be detected in urine samples longer than they can be detected in blood samples. One limitation of the use of urine, however, is that it is very difficult to determine the pharmacological significance of the analytical finding, because urine concentrations will vary dramatically with the specific gravity of the urine.

Many medication control programs have been moving toward exclusively using blood samples, and the resulting serum or plasma collected from them, as the testing matrix. Even though, as previously mentioned, the concentration of drugs in the plasma/serum is often less than it is in urine, recent advances in technology have tremendously increased the sensitivity of analytical methods, generally rendering this disadvantage irrelevant. A major advantage of the use of plasma/serum harvested from blood samples is that the concentrations can more easily be correlated to pharmacodynamic effects if the relevant pharmacokinetic/pharmacodynamic studies have been conducted. A disadvantage to their use is the need for venipuncture, which is invasive and requires at the minimum a trained veterinary technician, if not a veterinarian.

Alternative matrixes, such as hair, have been investigated but their use is problematic. It would be extremely difficult to prove the time frame of exposure when a drug is found in a hair sample, and some horses may change hands several times in the course of the year. Saliva has also been used as a testing matrix, but because it is difficult to obtain sufficient volume to allow for a confirmatory analysis, its usefulness is limited.

Analytical Methods for Extraction

The goal of an extraction process is to isolate and concentrate the drug, referred to as an analyte, from the sample. One of the simplest and oldest extraction methods is a liquid–liquid extraction (LLE). In LLE a liquid biological matrix, such as urine or plasma, is mixed with an organic solvent that is not miscible with the sample. Most drugs are more soluble in the organic solvent than in the aqueous matrix of the sample, so they concentrate into the solvent during the mixing process. The solvent is separated from the aqueous phase and usually concentrated by evaporation to increase the concentration of the analyte in the final reconstitution buffer, which will increase the sensitivity of the assay. In solid-phase extraction (SPE) the organic matrix is passed through a column containing beads to which functional groups, such as hydrocarbons or ion exchange groups, have been bound. The analytes bind to the beads allowing the organic contaminants to be removed by washing the column. In the final step the column is buffered to a specific pH to facilitate release of the analytes, which are then removed from the column with a small amount of elution buffer. The buffer is generally removed by evaporation and the sample reconstituted in a solvent amendable to analysis. Analytes may also be extracted from the sample matrix by precipitation, which relies on differences in the solubility of the analytes and other compounds in the matrix. This process is commonly used to remove the proteins from plasma or serum, after which the resulting supernatant can be directly analyzed.

It is important to realize that different extraction processes may be more or less efficient at separating drug from the biological matrix. This can have significant regulatory ramifications because the final determination of the amount of drug present in the sample will depend to some extent on the extraction method used. So if two laboratories analyze the same sample using different extraction methods, the final concentrations of the analyte determined by the labs may be slightly different. The extraction efficiency is often determined during validation of an analytical method, but rarely is it factored into the determination of the final concentration in a biological sample.

Analytical Methods for Separation

The goal of the separation process is to isolate analytes from each other after extraction and prior to the detection process. The most common method used in forensic drug testing laboratories for the separation of analytes is chromatography. For a chromatographic separation the extracted sample is reconstituted in a mobile phase and passed through an immiscible stationary phase. Differences in the chemical characteristics of the analytes, such as polarity, size, and charge state, will cause them to have different rates of migration through the stationary phase. These differences, when optimized, result in the analytes moving through the column in discrete waves or bands, which can be collected or diverted to other instruments for further analysis.

One of the oldest types of chromatography is planar chromatography, where the stationary phase is bonded to a piece of glass or paper, and the mobile phase passes over it by either gravity or capillary action. Thin layer chromatography (TLC) is a type of planar chromatography that was used for many years in forensic drug testing laboratories as a primary screening test. Because it is possible for different analytes to have similar migration patterns, the findings are only presumptive and a second confirmatory method must always be employed. TLC is extremely labor intensive and not as sensitive as more modern chromatography methods, and therefore it is not used with much frequency today.

In column chromatography, the stationary phase is contained within a column and the mobile phase, either liquid (LC) or gas (GC), is passed through it by either gravity or most commonly positive pressure. In GC, samples are vaporized in a heated inlet kept in excess of 200°C and moved through the column by an inert carrier gas, such as argon, helium, or nitrogen. Typical GC columns are several meters long with an internal diameter of 1 mm or less. One of the limitations of GC analysis is that many of the analytes of interest to forensic drug testing laboratories are not stable at high temperatures. Therefore, they are often derivatized to other compounds to make them more stable and volatile. The derivatization process can be time consuming and it complicates the analysis, which is another of the drawbacks to GC methodology. GC systems are fairly straightforward to operate, however, and for some compounds GC can be a very efficient separation method.

In liquid chromatography the analytes in a sample are separated by utilizing the differences in their physiochemical characteristics as they pass through an absorptive column. Typical LC columns are 100–500 mm long with an internal diameter of 3 mm or less. In LC methods the characteristics of both the mobile and stationary phases can be modified to optimize analytical separation. Another advantage of LC analysis is that it uses aqueous mobile phases at room temperature. Most of the compounds of interest to forensic drug testing laboratories are quite amenable to separation by LC, and therefore it is the most common separation method used today.

Analytical Methods for Detection

Once the analytes have been extracted from the biological matrix and then separated from each other, they must be identified. The two most common methods used in forensic drug testing laboratories to identify analytes are absorption spectroscopy and mass spectrometry.

Absorption spectroscopy detection methods employ ultraviolet or visible light, capitalizing on the property that many molecules will absorb certain frequencies of light. The degree of absorbance is generally directly proportional to the concentration of the molecule in solution. Because most absorption spectroscopic methods are very robust and relatively inexpensive, they are commonly used for quantitative analysis. One of the limitations of absorption spectroscopy, however, is that two different analytes can have overlapping absorption spectra and similar elution times, making them difficult to differentiate. In addition, the presence of chemical and/or spectral interferences can cause erroneous detector responses resulting in quantitative errors. As such absorption spectroscopic methods are not appropriate for definitive confirmation of the identification of an analyte, but are used to confirm overages of permitted medications, which have established thresholds.

In mass spectrometry (MS), following extraction and separation, the analytes are serially injected into the mass spectrometer for identification. While many different types of mass spectrometers are commercially available, the type most commonly used in forensic drug testing laboratories bombards the analyte with a beam of electrons that causes the molecules to become ionized. While some of these ions will remain intact, referred to as precursor ions, many will fragment into smaller ions and neutral fragments. The precursor ions and the product fragments are separated in electric or magnetic fields based on their mass to charge ratio and then serially passed into a detector that measures the abundance of each ion. A plot of the abundances of the precursor and product fragment ions versus their mass to charge ratios is referred to as the compound's mass spectrum (Figure 57.1). The highest molecular weight peak in a spectrum usually represents the parent molecule minus a single electron (i.e., ionized), and is referred to as the molecular ion. The mass spectrum of the analyte is compared to a computerized database of mass spectra, referred to as a library, or to an authenticated standard of a known compound. Because the fragmentation pathways for many molecules are well characterized and extremely reproducible, unambiguous identification of a compound can be achieved using MS. Even analytes with the same nominal mass can be differentiated, because they will produce different fragmentation patterns. Because the abundance of the ions is directly proportional to the concentration of the analyte in the solution, extremely accurate quantitation is possible using MS methods. One of the disadvantages of MS is that it requires highly trained analysts to develop the methods and interpret the data. Nevertheless, because of the high degree of specificity inherent in the results, mass spectrometry has become the de facto standard method for drug identification in forensic drug testing programs.

In practice, the separation and detection processes are combined. An LC or GC instrument is placed in front of the mass spectrometer leading to the common designation of LC/MS or GC/MS. In addition, newer instrumentation can repeat the ionization and fragmentation processes on the original fragmentation ions, so-called LC/MS/MS or LC/MSn. This process can dramatically increase both the accuracy and the sensitivity of the method.

Testing Scheme Overview

Regardless of the type of sample collected (i.e., blood, urine, hair, etc.) the testing procedure must take into consideration both scientific and legal issues. An extremely important legal aspect of the process is the chain-of-custody documentation, which is a tamper-resistant paper or electronic trail indicating where the sample has been and who has had custody of it at all times. For this reason the actual drug testing process begins when the sample is collected. If there are questions about the integrity of that process, it puts the results of the final analysis in to question. For example, because many modern mass spectrometric techniques can detect quantities of drugs and medications in the picogram to femtogram range, special care must be taken by the sampling personnel to prevent contamination from environmental

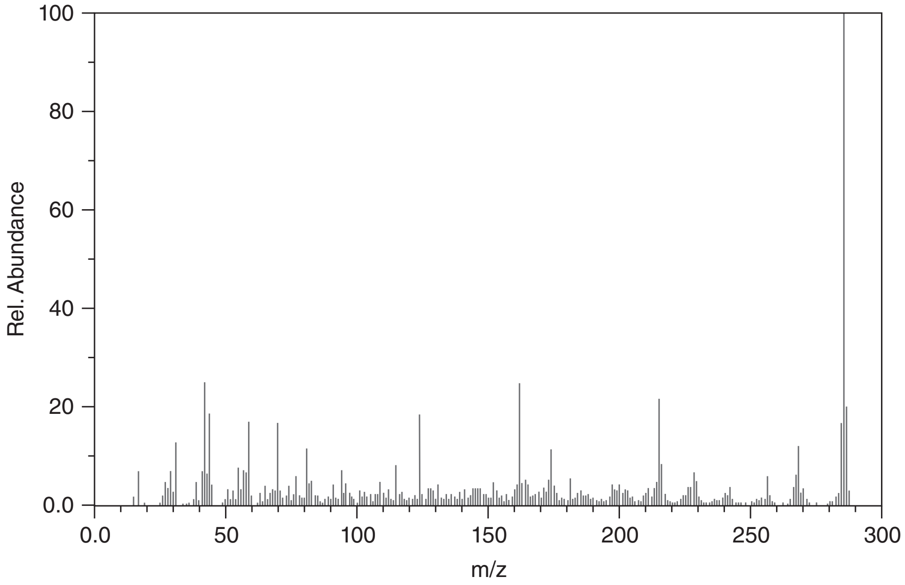

Figure 57.1 Mass spectrum of morphine. Source: National Institute of Standards and Technology.

sources during the collection process. Only clean, new, sample collection vessels should be used and personnel should wear appropriate attire, such as clean coveralls and disposable gloves. In addition, no eating, drinking, or smoking should be permitted at the collection location.

Once a sample is collected, a small aliquot is usually transferred to a separate container, which is referred to as the split, referee, or B sample, and both are sealed with tamper-proof evidence tape and secured in locked containers or coolers for transport to the testing laboratory. If the original sample is found to contain a nonpermitted substance or an overage of a permitted medication, the referee or B sample can be used to confirm the findings of the original analysis. In some cases the referee sample is sent to the laboratory with the original sample and in other cases it is stored at a separate facility. To prevent degradation, nonfrozen samples should be kept cold and shipped overnight to the laboratory. Otherwise the samples should be frozen and kept frozen throughout the shipping process.

The samples are shipped to the laboratories with a manifest that generally contains only limited information regarding the samples. Each sample will have a unique identification code and generally the manifest sheet will indicate the event or racetrack where the sample originated, the day the samples were collected, and the number of the class or race that the animal competed in that day. The laboratory does not know the name of the animal, the trainer, rider or driver, or any other identifying information regarding the animal, other than the sex in some cases. Maintaining anonymity in the testing process is crucial to ensuring its integrity and the reputation of the laboratory for fair and equitability treatment.

Once at the laboratory, the samples will generally be logged into the laboratory information management system and stored in a secure refrigerator or freezer, as appropriate, until they are analyzed. In the first step of the process all of the samples are subjected to a series of screening tests. Currently, the state of the art screening would be a combination of acid, basic, and neutral pH extractions with and without an enzyme hydrolysis step, designed to liberate conjugated metabolites, followed by LC-MS screening. Some laboratories include an enzyme-linked immunoassay (ELISA) screen and other may still use a TLC analysis, although this is becoming less common.

If any of the screening tests are positive, the sample is determined to be suspicious and sent for confirmational analysis. As a general rule, confirmation will always entail a mass spectral identification. LC/MS is the most common methodology used today in forensic drug testing laboratories, although GC/MS is also still occasionally used.

Referee Sample Analysis

As described above, before a reputable laboratory reports that a sample contains a nonpermitted substance, the sample has undergone multiple screening and confirmation tests using several different analytical methods. Nevertheless, a referee or B samples analysis is permitted in many different drug and medication rules. The referee sample is analyzed by an independent laboratory approved by the regulatory body, and, if that laboratory does not confirm the presence of the nonpermitted substance, than generally no regulatory action is taken. There are variations on how these programs are executed, so veterinarians may want to review the process with his or her client when they are discussing the applicable drug and medication rule.

Factors Affecting Withdrawal Times

A withdrawal time can be defined as the number of hours, day, weeks, etc. that should elapse following the last administration of a drug in order to avoid the animal having a detectable concentration of a nonpermitted drug in a sample collected during or after a competition. Veterinarians are familiar with withdrawal times from food animal medicine, and often want to know specific withdrawal times for therapeutic medications commonly used in animals competing in athletic events. Unfortunately, it can be difficult for laboratories to generate that information, because so many factors can affect the rates at which drugs are eliminated from the body. For example, there is often a large dose range for therapeutic medications, and the duration of treatment also varies. Some drugs, such as clenbuterol and isoxsuprine, can accumulate in the body leading to extremely long withdrawal times if the laboratory uses a sensitive analytical method. The route by which the medication is administered can also affect the withdrawal time. Drugs administered intravenously will generally be eliminated in a predictable manner, whereas drugs administered orally or subcutaneously may have more variable absorption patterns, which will in turn affect the time course of drug elimination. Laboratory factors can also affect withdrawal times because different labs may use different analytical methods with different limits of detection (LOD = the lowest concentration of an analyte the method can reliable differentiate from the background). Many of these concepts applied to food animal withdrawal times are similar and are discussed in Chapter 61.

For racing horses, the RMTC and ARCI have generated recommended withdrawal times for a number of therapeutic substances (www.rmtcnet.com) and most US forensic drug testing laboratories have agreed to follow the associated recommended detection limits. In a similar manner, the USEF has published recommended withdrawal times for medications commonly used in horses competing under their Therapeutic Substance Rule (http://www.bevet.com/files/usefmedicationinformation pdf.pdf).

Thresholds, Reporting Levels, and Cutoffs

As analytical chemistry methods have improved, the smallest amount of a drug that can be detected in a bodily fluid has progressively decreased. LODs in the picogram/ml range are not uncommon in many forensic drug testing laboratories. Because the sensitivity of the testing is so high, administration of some medications days or even weeks before a race or event can result in a positive drug test. For example, following 30 days of dosing, clenbuterol was still readily detectable for 3 weeks after the last administration (Kynch et al., 2014). In addition, contamination of the animal's diet with feedstuffs that naturally contain small amounts of prohibited substances can also be the source of positive drug tests. For example, cocoa husks, which may be used in some feeds as filler, contains theobromine, a xanthine related to caffeine and considered a prohibited substance. In a similar manner, plants in the family of *Datura* contain scopolamine and other alkaloids and may be found growing around barns and pastures.

Table 57.1 Commonly accepted reporting levels for substances with environmental sources

Arsenic	3 μg/ml in urine
Salicylic acid	625 μg/ml in urine or 5.4 μg/ml in plasma
Theobromine	2 μg/ml in urine

Regulatory authorities have in some cases have adopted concentrations for certain substances below which the laboratory will not report their presence as a violation of the drug rule. There are various names for these concentrations including thresholds, reporting levels, cutoffs, etc. There are two types of analytes for which these reporting levels are adopted. First, there are some substances that can commonly be found in the horse's food or environment, which makes it difficult for trainers to prevent their horses from coming into contact with them (Table 57.1). Second, because many therapeutic agents can now be detected for much longer than they are pharmacologically active, reporting levels have also been developed for a number of therapeutic agents by some industry stakeholder groups, such as the RMTC (Table 57.2). Veterinarians need to be aware that the reporting levels in place will vary with each regulatory authority. In addition, the adoption of these reporting levels remains controversial with some industry stakeholders, so veterinarians should be aware that the levels may vary depending on the jurisdiction and the equestrian discipline.

Current Controversies

Furosemide

Furosemide is a loop diuretic that acts by inhibiting luminal Na^+-K^+-$2Cl^-$ transporters in the thick ascending limb of the Loop of Henle. By blocking the reabsorption

Table 57.2 Racing Medication and Testing Consortium recommended reporting levels for some commonly administered therapeutic agents

Medication	Withdrawal guideline	Threshold	Route of administration	Experimental dose
Betamethasone	7 days	10 pg/ml of plasma or serum	Intraarticular	9 mg total in one articular space
Dexamethasone	72 hours	5 pg/ml of plasma or serum	Intravenous	0.05 mg/kg
Firocoxib	14 days	20 ng/ml of plasma or serum	Oral	0.1 mg/kg for 4 days
Methocarbamol	48 hours	1 ng/ml of serum or plasma	IV/Oral	15 mg/kg IV; 5g orally

of Na^+, Cl^-, and water it causes significant diuresis. In the USA and Canada, furosemide is frequently administered no less than 4 hours prior to racing to horses that suffer from exercise-induced pulmonary hemorrhage (EIPH). In the rest of the world, furosemide is considered a forbidden substance in all horses, regardless of their EIPH status.

Whether furosemide is therapeutically beneficial for horses that suffer from EIPH is extremely controversial. It was originally hypothesized that by decreasing the circulating plasma volume, furosemide might decrease the high intravascular pulmonary capillary pressure that has been proposed to be the underlying pathophysiological mechanism of EIPH (Hinchcliff and Muir, 1991). Numerous studies conducted under both laboratory and racetrack conditions have yielded conflicting results as to its efficacy in decreasing the severity of EIPH (Sweeney and Soma, 1984; Pascoe et al., 1985). A large, well-controlled study conducted on race horses in South Africa, however, did demonstrate, quite compellingly, that furosemide decreased the incidence and severity of EIPH (Hinchcliff et al., 2009). There is also substantial evidence, however, from studies conducted under both laboratory and racing conditions that furosemide can enhance athletic performance in horses (Soma and Uboh, 1998). Despite the evidence that furosemide may be of therapeutic benefit to horses that suffer from EIPH, at the present time some racing industry stakeholders have suggested that it should be a forbidden substance in US racing. The argument made is that it supports a negative stereotype of racing, where horses have to be "drugged" in order to compete and that making it a banned substance would be consistent with racing regulations worldwide.

Anabolic Steroids

Until 2009, the use of anabolic steroids in racing horses in the USA, while not technically permitted, was basically allowed because most laboratories were not analyzing postrace urine samples for their presence. This was in stark contrast to most racing jurisdictions globally, where anabolic steroids were considered forbidden substances and where laboratories judiciously tested for their presence. Following a series of dramatic catastrophic injuries in high-profile races in 2008 that resulted in a significant amount of negative press, racing jurisdictions in the USA began to adopt regulations limiting the use of anabolic steroids. It should be noted that a direct link between treatment with anabolic steroids and an increased risk of suffering a catastrophic injury has never been made. The RMTC recently released recommendations for plasma thresholds for a number of anabolic steroids commonly used in racehorses, calling for significantly prolonged withdrawal times (Table 57.3). Previous thresholds were adopted in urine, but the results of recent studies have suggested that boldenone and nandrolone can be formed ex vivo in the urine by enzymatic conversion of testosterone (Guan et al., 2012; Soma et al., 2012). The ex vivo conversion of testosterone to boldenone was confirmed in a urine sample collected from a Standardbred stallion in Australia (author's personal experience). In addition, the spontaneous conversion of testosterone to both nandrolone and boldenone has been confirmed in urine samples collected from intact cattle (Poelmans et al., 2005; Le Bizec et al., 2006; Dervilly-Pinet et al., 2011). It may be that contamination of equine urine samples with fecal bacteria is the mechanism by which the conversion

Table 57.3 Plasma thresholds for anabolic steroids recommended by the Racing Medication and Testing Consortium

Anabolic steroid	Threshold	Withdrawal recommendation
Boldenone	25 pg/ml for all horses regardless of sex	82 days
Nandrolone	25 pg/ml for geldings, fillies, and mares (male horses other than geldings will not be tested for nandrolone in blood)	35 days
Stanzolol	25 pg/ml for all horses regardless of sex	47 days
Testosterone	25 pg/ml for geldings, fillies and mares and a confirmatory limit of 2 μg/ml for male horses other than geldings, which regulates a 30-day withdrawal time	30 days

occurs, but this has not been confirmed. One of the arguments in favor of the use of plasma as the testing matrix, instead of urine, is that bacterial contamination is exceedingly rare, and therefore ex vivo formation may be less likely to occur. If a racing jurisdiction adopts the RMTC thresholds the extremely long withdrawal times make the use of anabolic steroids in racehorses in training in that jurisdiction practically impossible.

Recombinant Products

Traditional drug testing processes have been focused on small drug molecules. Since the introduction of glycoprotein and peptide hormones, such as recombinant erythropoietin (rEPO) and recombinant growth hormone (rGH), their detection and differentiation from endogenous analogs has been a challenge for forensic drug testing laboratories. These are large molecules and, depending on whether their origin is equine or human, they may be identical or almost identical to the endogenous molecule. In addition, after administration their effects on the body last far longer than current analytical methods are capable of detecting their presence in urine or blood samples.

The endogenous hormone erythropoietin, which is produced by the kidneys, regulates erythrocyte and hemoglobin production in mammals. In humans use of an erythropoietin peptide produced by recombinant technology (rEPO) has been shown to increase aerobic athletic performance by increasing the oxygen carrying capacity of the blood (Audran et al., 1999; Birkeland et al., 2000). Horses, however, possess a contractile spleen that can release up to 12 liters of blood during periods of stress, excitement, or exercise (Toutain, 2010). Because horses are in essence natural blood dopers, it has always been questioned whether rEPO administration would enhance athletic performance in equine athletes. In one study in unfit horses rEPO enhanced aerobic capacity, but did not improve athletic performance (McKeever et al., 2006). The effect of rEPO on fit horses, however, has not been determined. In addition to possible performance enhancing effects, rEPO also has been associated with the development of severe anemia in horses (Piercy et al., 1998; Woods et al., 1997). All rEPO products are derived from the human peptide sequence and it appears the small differences between the final structure of the human and equine peptide are significant enough for the body to recognize the protein as foreign. The antibodies generated against the human protein cross-react with the endogenous equine hormone, preventing it from functioning, resulting in anemia, and in some cases death. Therefore, regardless of its performance enhancing effects, or lack thereof, rEPO is generally not permitted to be administered to horses subject to medication control programs.

A great deal of effort and money has been expended to develop methods to detect the administration of rEPO to horses. In one study following IV administration of rEPO, the peptide could be readily detected in urine by ELISA for up 10 hours postdosing, but by 48 hours plasma concentrations had returned to baseline (Tay et al., 1996). Using LC/MS/MS methodology rEPO was detectable for several days following administration (Guan et al., 2007). The half-life of equine red blood cells is relatively long at 140 days, however, and therefore if there were benefits to the use of rEPO, they would last long after it could be detected by current testing methods. This situation has led to adoption of out of competition testing in many jurisdictions. A number of states have mandated that blood can be collected from any horse on racetrack grounds, regardless of whether the horse is actually entered to race. These samples can then be analyzed for the presence of rEPO.

Recombinant growth hormone (rGH) has been available in Australia for a number of years. Sold under the brand name EquiGen™ Injection, it is a freeze-dried form of methionyl equine somatotropin (eST) or equine growth hormone produced by recombinant DNA technology. In one study the athletic performance of unfit mares was not enhanced by rGH administration (McKeever et al., 1998). Regardless, it is considered a nonpermitted substance in all regulated competitions, although its detection is extremely problematic at this time.

Pharmacovigilance

John D. Baker, Susan J. Bright-Ponte, and Lee Anne M. Palmer

Introduction

FDA Overview

The US Food and Drug Administration (FDA) is a regulatory, science-based federal agency responsible for protecting and promoting the public health through monitoring and regulation of a variety of products necessary for the health and well-being of consumers. The FDA's jurisdiction includes most food products (other than meat and poultry), animal feed and pet food, human and animal drugs, human dietary supplements, medical devices, veterinary devices, therapeutic agents of biological origin for humans (e.g., vaccines), radiation-emitting products for consumer, medical, and occupational use, cosmetics, and tobacco products.

FDA is an agency within the Department of Health and Human Services and is organized into five major offices under the Office of the Commissioner. The Center for Veterinary Medicine (CVM) and the Center for Food Safety and Applied Nutrition (CFSAN) report directly to FDA's Office of Foods and Veterinary Medicine (FDA, 2017a).

Center for Veterinary Medicine

Among other things, the Center for Veterinary Medicine is responsible for ensuring that animal drugs, including drugs intended for use in or on animal feed, are safe and effective for their intended uses and that food from treated animals is safe for human consumption. Before a new animal drug can be legally marketed in the United States, it must be approved by the FDA on the basis of quality, safety, and efficacy. When the drug is to be approved for use in food-producing animals, safety to the target animal species must be demonstrated, in addition to safety of food products derived from the treated animals that are intended for human consumption. Once approved products are on the market, the Center monitors the use of the products through surveillance, compliance, and pharmacovigilance programs. Currently, the Center for Veterinary Medicine is organized into six offices. Information about each office and their roles and responsibilities can be found on CVM's web site (FDA, 2017b).

CVM's Office of Surveillance and Compliance (OS&C) has primary responsibility for several of the Center's core functions, including compliance-related actions, postapproval monitoring, and animal feed safety. Within OS&C, the Division of Veterinary Product Safety (DVPS) is responsible for monitoring the safety and effectiveness of marketed animal drugs and devices, and the safety of pet food, through review and analysis of adverse experience reports. The information obtained from review and analysis of these reports helps CVM make decisions about product safety, potentially leading to regulatory actions, label revisions, or other changes necessary to ensure the safe and effective use of a product. Submitted adverse experience reports are maintained in a database used by OS&C to conduct postapproval surveillance and pharmacovigilance activities.

Overview of FDA's Postapproval Surveillance Program

Although CVM has a rigorous preapproval process for animal drugs, well-conducted randomized controlled clinical trials may not be of sufficient size to identify every safety problem. Once a product is marketed, there is a substantial increase in the number of patients exposed to the drug, including animals with coexisting medical conditions and those being treated with concomitant medications and biologic agents such as vaccines. There are potential food interactions as well. Additional information about medical product safety and effectiveness is obtained after a product is marketed and used under actual field conditions in large diverse populations of animals. This information is used to complete the safety profile of a product and helps to ensure that drug product labeling is adequate and accurate. Ultimately, this information will assist practitioners in making informed decisions to minimize risks while maximizing benefits of the drugs used in animals.

Pharmacovigilance and Adverse Event Reporting at CVM

Pharmacovigilance

Pharmacovigilance, as defined by the World Health Organization (WHO), is "the science and activities relating to the detection, assessment, understanding, and prevention of adverse effects or any other drug-related problems" (WHO, 2006). The goal of a veterinary pharmacovigilance program is to ensure the continued safety and effectiveness of animal drugs once they are being used in a wide and diverse population of animals.

In general, the role of a pharmacovigilance program is to identify safety signals that, upon further evaluation, may lead to the discovery of previously unidentified or unrecognized adverse drug events and associated risk factors that were not identified in the preapproval evaluation of the product. These adverse events may be related to previously unrecognized pharmacological effects of the drug, idiosyncratic effects, drug–drug interactions, drug–food interactions, drug–disease interactions, factors specific to certain patient populations, individual patient factors, medication errors, product defects, or other factors, such as the reaction being too uncommon to be identified in the small number of animals in which the drug is tested in preapproval studies (CIOMS, 2010). Spontaneous reports of adverse drug experiences, medication errors, and product defects comprise the primary data source upon which CVM's postapproval pharmacovigilance efforts depend. Also, data from postapproval clinical studies and from the scientific literature may be utilized. Limitations of utilizing spontaneous adverse drug experience (ADE) reporting databases for pharmacovigilance activities include the significant underreporting of ADEs, limited detail in submitted reports, and reporting biases (Strom and Kimmel, 2006). Given the variability in reporting and the many factors that affect reporting, it is well accepted that reporting rates cannot be used to reliably estimate incidence rates of ADEs in the exposed population, and that comparison of reporting rates between products or between countries cannot be used to determine risk. Despite these limitations, the monitoring and evaluation of ADE reports is very important to help ensure that the overall balance of risks and benefits of a particular drug remain acceptable. Additionally, it allows for communication of essential drug safety information to veterinarians and others involved in the treatment of animals.

Adverse Drug Experience – Definition

An *adverse drug experience*, as currently defined by 21 CFR 514.3, is "any adverse event associated with the use of a new animal drug, whether or not considered to be drug related, and whether or not the new animal drug was used in accordance with the approved labeling (i.e., used according to label directions, or used in an extralabel manner, including but not limited to different route of administration, different species, different indications, or other than labeled dosage). Adverse drug experience includes, but is not limited to:

1) An adverse event occurring in animals in the course of the use of an animal drug product by a veterinarian or by a livestock producer or other animal owner or caretaker.
2) Failure of a new animal drug to produce its expected pharmacological or clinical effect (lack of expected effectiveness).
3) An adverse event occurring in humans from exposure during manufacture, testing, handling, or use of a new animal drug."

ADE reports submitted to CVM can involve approved or unapproved animal drugs, human drugs used to treat animals, events in humans exposed to animal drugs, and events related to devices used in animals.

Adverse Drug Experience (ADE) Reporting

CVM encourages veterinarians or animal owners who want to report an adverse drug event to an FDA-approved product in an animal or human, to contact the product manufacturer. In the USA, ADE reporting by veterinarians and consumers is voluntary. However, manufacturers and distributors of FDA-approved animal drugs may be subject to the mandatory ADE reporting requirements in 21 CFR 514.80, as discussed further below in this section. All unsolicited reports from veterinarians or consumers, received by the FDA via either the voluntary or mandatory route, are called spontaneous reports.

Consumers and veterinarians can report adverse drug events directly to CVM by downloading a fillable Form FDA 1932a from CVM's website (FDA, 2017c). This form should be printed and sent or emailed to FDA. Veterinarians and consumers can also report information to CVM by calling the CVM hotline at 1-888-FDA-VETS. In response to the inquiry, CVM can provide a Form FDA 1932a so that it can be completed by the reporter and mailed to CVM. More information about voluntary reporting of adverse events by consumers and veterinarians is available on CVM's website (FDA, 2017d). The regulations that address the spontaneous reporting obligations for manufacturers and distributors of FDA-approved animal drugs are contained in 21 CFR 514.80, "Records and reports concerning experience with new animal drugs for which an approved application is in effect."

ADE reports are classified into essentially four categories: (1) 3-day field alerts, (2) 15-day alert initial reports, (3) follow-up reports, and (4) periodic reports.

As defined in 21 CFR 514.80(b)(1), 3-day field alert reports contain information regarding product and manufacturing defects that may result in serious ADEs. Reports of serious, unexpected ADEs are submitted as 15-day alert or "expedited" reports. As required in 21 CFR 514.80(b)(2), these reports must be submitted on Form FDA 1932 to FDA by the applicant within 15 working days of first receiving the information. Follow-up reports are submitted on Form FDA 1932 by the applicant if significant new information is revealed during their investigation of ADEs that are the subject of 15-day alert reports. Reports of ADEs that are not serious and unexpected and reports of product defects that are not expected to result in serious ADEs are submitted in the periodic drug experience report, which is submitted every 6 months for the first 2 years after approval and annually thereafter.

ADE reporting to CVM has increased dramatically over the last decade. CVM received 28,825 ADE reports for the fiscal year 2004 and 91,592 for the fiscal year 2015 (Figure 58.1). Some of the reasons for the significant increase include an increase in number of drug approvals, especially for companion animals, label information providing contact numbers for drug companies, and the interest of the public in reporting perceived product problems. Wide access to the media and internet has also increased the public's general awareness about drug safety.

Approved versus Unapproved Drugs

ADE submission is required only from companies marketing FDA-approved and conditionally (FDA, 2017e) approved animal drugs. Currently, there are no requirements for submitting ADEs for unapproved animal drugs (animal drugs which have not gone through FDA's approval process) or human drugs used in animals. Exceptions to this are those drugs on FDA's Index of Legally Marketed Unapproved New Animal Drugs for Minor Species (the "Index"). These drugs are legally marketed for a specific use in certain minor species. Many approved animal drugs can be identified by the presence of a New Animal Drug Application (NADA) number on the label, or an Abbreviated New Animal Drug Application (ANADA) number for generic drugs, or a C-NADA number in the case of conditionally approved drugs, although these identifiers on labeling are not currently required by regulation. Veterinarians and/or animal owners are encouraged to report ADEs for unapproved animal drugs, including compounded products, to CVM using the Form FDA 1932a.

Animal Devices

Though no form of premarket approval is currently required for devices used in veterinary medicine, FDA does have regulatory oversight over veterinary devices and can take appropriate regulatory action if a device is misbranded, mislabeled, or adulterated. A few examples of devices commonly used in animals include suture material, certain types of bandage materials, intravenous catheters, anesthetic machines and equipment, as well as

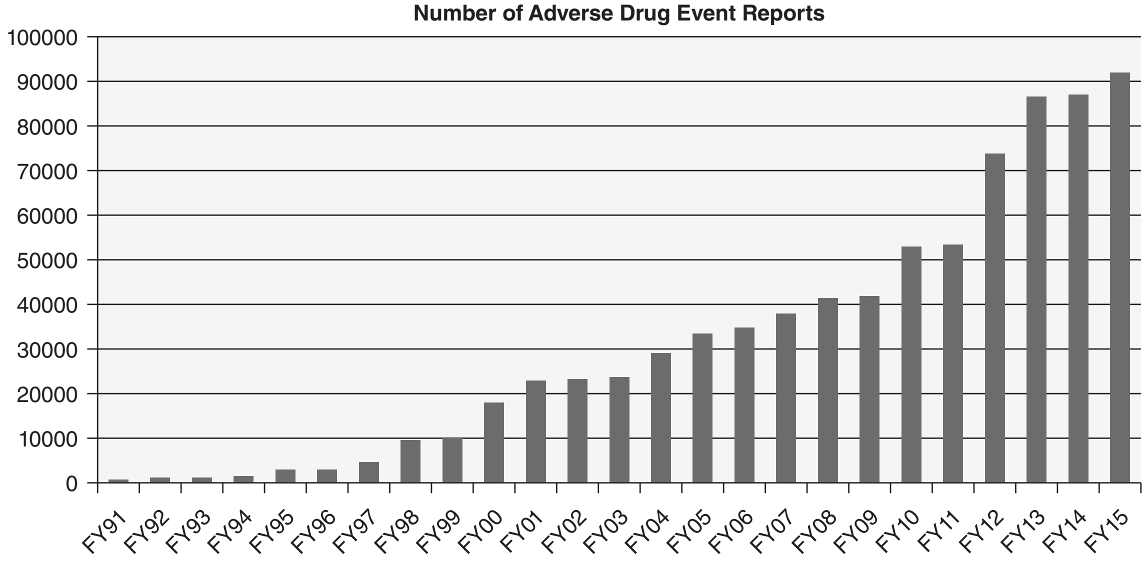

Figure 58.1 Number of adverse drug event (ADE) reports received by CVM from fiscal years (FY) 1991 through 2015.

imaging equipment. It is the responsibility of the manufacturer and/or distributor of these articles to assure that animal devices are safe, effective, and properly labeled. Although not required by regulation, CVM accepts reports from manufacturers and distributors of veterinary devices of adverse events associated with marketed devices. Most adverse event reports that CVM receives for animal devices are reported directly by veterinarians or animal owners.

Product Defects

Animal drugs, both prescription and over-the-counter (OTC), must be manufactured in accordance with Current Good Manufacturing Practices (cGMPs) according to regulation. FDA inspects manufacturing facilities before a drug application can be approved. Adherence to cGMP regulations assures the identity, strength, quality, and purity of drug products by requiring that manufacturers of drugs adequately control manufacturing operations.

Reporting Product Defects

A product defect is defined by regulation as "the deviation of a distributed product from the standards specified in the approved application, or any significant chemical, physical, or other change, or deterioration in the distributed drug product, including any microbial or chemical contamination. A manufacturing defect is a product defect caused or aggravated by a manufacturing or related process. These defects are generally associated with product contamination, product deterioration, manufacturing error, defective packaging, damage from disaster, or labeling error. For example, a labeling error may include any incident that causes a distributed product to be mistaken for, or its labeling applied to, another product." As discussed previously, reporting requirements for product defects are codified in 21 CFR 514.80. Three-day field alert reports involve product defects that may result in a serious adverse event. Product defects that do not have the potential for serious adverse events are reported directly to CVM in periodic reports. Examples of product or manufacturing defects that may result in serious adverse events include, but are not limited to, improperly labeled products, subpotent products leading to lack of effectiveness, superpotent products leading to potential toxicity, lack of sterility or particulate matter in injectable products, and failure of syringe-locking devices leading to accidental overdose of the drug (Bataller and Keller, 1999). Firms work with the appropriate FDA Field Office to accomplish corrective actions for product and manufacturing defects.

Medication Errors

The National Coordinating Council for Medication Error Reporting and Prevention (NCCMERP) defines a medication error as "any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care products, procedures, and systems, including prescribing; order communication; product labeling, packaging, and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use."(NCCMERP, 2012). Of these, prescribing errors have been documented to cause the most harm in human patients (Strom and Kimmel, 2006). In 1992, FDA's Center for Drug Evaluation and Research (CDER) began monitoring human medication error reports that are forwarded to FDA from the United States Pharmacopeia (USP) and the Institute for Safe Medication Practices (ISMP).

In 2008, CVM began a patient safety initiative to prevent medication errors in animals. Medication errors can occur in several settings, including veterinary clinics and hospitals, universities, and human and veterinary pharmacies. Medication errors may occur for a variety of reasons, including, but not limited to:

- incomplete patient information (for example, not knowing about patients' allergies, other medicines they are taking, previous diagnoses, and lab results);
- unavailable drug information (such as lack of up-to-date warnings);
- miscommunication of drug orders, which can involve poor handwriting, confusion between drugs with similar names, misuse of zeros and decimal points, confusion of metric and other dosing units, and inappropriate abbreviations;
- lack of appropriate labeling as a drug is prepared and repackaged into smaller units;
- environmental factors, such as lighting, heat, noise, and interruptions, which can distract health professionals from their medical tasks (AHA, 2015).

Unclear medical abbreviations are one of the most common causes of medication errors.

Not all practitioners interpret abbreviations uniformly, and, therefore, the intended meaning is not always conveyed. This can occur for both written and typed prescriptions. Pharmacists may be unfamiliar with some of the medical abbreviations commonly taught in veterinary school. For example, the abbreviation "SID" (once daily) used on animal drug prescriptions is not recognized by most pharmacies and may be interpreted as "BID" (twice daily) or even "QID" (four times daily), resulting in drug overdoses for animal patients (Kim-Jung, 2010).

CVM has received several reports of medication errors of this type. Other commonly misinterpreted abbreviations include the use of “U” for units (“U” misread as zero), and the use of “μg” or “mcg” for microgram (mistaken for “mg”).

NCCMERP encourages the avoidance of abbreviations in the prescribing of medications (NCCMERP, 2005). Another common cause of medication errors is the use of trailing zeros and not using leading zeros when writing doses in medical records or on prescriptions. For example, a “5 mg” dose written with the trailing zero as “5.0” mg” can easily be misread as “50 mg.” Similarly, a “0.5 mg” dose written without the leading zero as “.5 mg” can be mistaken for “5 mg.”

FDA has worked to increase the safe use of drug products by minimizing user errors attributed to unclear nomenclature, labels, labeling, and packaging design of drug products.

Pet Food Adverse Event and Product Problem Reporting

Reporting of pet food adverse events to FDA CVM is important, and can provide an early warning of emerging food-borne diseases and problems. Additionally, owners and/or veterinarians are encouraged to contact the product manufacturer or distributor on the product label to report potential problems that may be associated with the product and/or packaging, although manufacturers are not required to forward those reports to CVM. Pet food products include pet foods, treats, puppy and kitten milk replacers, pet nutritional supplements, and pet beverages (FDA, 2017f). Examples of pet food product problems include foul odors, swollen cans or pouches, leaking containers, or foreign objects. Adverse event reports can include pet illnesses or clinical signs that an animal owner or veterinarian believes are associated with pet food product consumption. The quality of adverse event reports is enhanced if the following information is included in the report: the number of animals fed, the number that experienced the problem, the species and breed, and, if possible, the age, weight, and sex as well as the overall state of health of the animal before the adverse event. Other helpful information includes the names of any medications or other products the animal was being given or fed prior to the adverse event. The brand name, package type, package size, UPC (Universal Product Code), lot number, and use by date (found on the product packaging) as well as name and address of the manufacturer or distributor of the product and name of store where purchased is helpful information to report. Additional useful information includes the length of time between feeding the suspect food and clinical sign(s) occurrence and the amount of food consumed. The FDA website gives more information about how to report a pet food problem (FDA, 2017g).

The FDA receives reports related to pet food adverse events and product problems primarily through two channels: the Safety Reporting Portal (SRP), and the FDA District Offices. Both are components of the Pet Food Early Warning and Surveillance System (PFEWSS), which was created after the passage of the Food and Drug Administration Amendments Act (FDAAA) of 2007 in response to the melamine and cyanuric acid contamination of pet food that led to the largest recall in history of pet food in the United States. During the initial weeks of this crisis, FDA received over 11,000 pet food complaints. The combination of melamine and cyanuric acid contamination led to the development of crystals within the kidneys of dogs and cats consuming the adulterated pet foods, leading to renal failure (Dobson et al., 2008).

As part of fulfilling the requirements for a PFEWSS, the Safety Reporting Portal (SRP) was developed and went online in May of 2010 (www.safetyreporting.hhs.gov). Animal owners, concerned citizens, and veterinarians can use the portal’s pet food questionnaire to report pet food-related problems directly to CVM. Medical records, laboratory reports, photographs, and other documents can be uploaded with the SRP pet food report, and provide valuable medical information. Voluntary pet food reports are known as PFRs (Pet Food Reports). In 2014, the Livestock Food Reporting portion of the SRP opened. Consumers and veterinarians can report adverse events and product problems related to livestock feeds through this section of the portal, which is also accessed at www.safetyreporting.hhs.gov. These reports are known as LFRs (Livestock Food Reports). Another part of the SRP is the Reportable Food Registry (RFR) (www.fda.gov/Food/ComplianceEnforcement/RFR/default.htm) for mandatory reporting of specific types of product problems by manufacturers. RFR reports are submitted by manufacturers when there is a reasonable probability that an article of food will cause serious adverse health consequences. The requirements for RFR reporting are prescribed by the FDAAA of 2007.

An example of a problem that was identified through adverse event reporting using the Safety Reporting Portal is thiamine deficiency in a brand of canned cat food. A cat was diagnosed with thiamine deficiency after strictly eating one brand of canned cat food. The veterinary neurologists reported to CVM using the SRP soon after it opened in 2010, leading to a prompt product recall by the manufacturer (FDA, 2017f).

Another route that is available for reporting of pet or livestock food adverse events or product problems by owners and veterinarians is to call the FDA Consumer Complaint Coordinator that serves the geographic region in which the reporter lives. A list of the FDA Consumer Complaint Coordinators is available on the FDA website (FDA, 2017h). Early detection of pet food and animal feed problems is facilitated by reporting to the

FDA through these channels, and can lead to faster intervention by the FDA and manufacturers.

Reporting of Adverse Events associated with pesticides or vaccines

Adverse events in animals may occur in association with the administration of pesticide products or vaccines. Veterinarians can report pesticide related adverse events online to the Environmental Protection Agency (EPA) and the National Pesticide Information Center (NPIC) (http://pi.ace.orst.edu/vetrep/). FDA approves some flea and tick products as animal drugs while the Environmental Protection Agency (EPA) registers others as pesticides. This is further discussed in Chapter 43 of this textbook. The regulating agency can be identified on a product's label (FDA, 2017i). Consumers can report adverse events associated with pesticides by calling 1-800-858-7378**;** or by email at npic@ace.orst.edu. Animal vaccine-related adverse events can be reported to the vaccine manufacturer or to the Center for Veterinary Biologics at the USDA (USDA APHIS, 2011).

Evaluation of Adverse Drug Experience Reports

CVM's ADE Review Process

CVM receives ADE reports in both paper and electronic format. Voluntary reports are received by the FDA on paper or by email (Form FDA 1932a). Mandatory ADE reports (from manufacturers) submitted electronically are transmitted via the Electronic Submissions System (ESS), and the Rational Questionnaire (RQ) in the SRP (FDA, 2017j). The ESS is integrated with the FDA Electronic Submissions Gateway (ESG) allowing gateway-to-gateway submission of individual or batched reports from manufacturers. Individual mandatory reports can also be submitted by manufacturers using the SRP rather than the gateway. However, at this time, the SRP is not configured to accept adverse drug event reports from veterinarians or consumers. All reports, mandatory and voluntary, enter the CVM ADE database for analysis and archiving.

As previously described, preapproval data is limited in terms of the number of animals in which the product is evaluated, so new safety concerns can emerge once recently approved drugs enter the marketplace and are used in thousands of animals. In consideration of the large volume and complexity of ADE data which is received, CVM utilizes a triage system and focuses on recently approved drugs to complete the safety profile of the product. These products are assigned to individual Safety Reviewers in the Division of Veterinary Product Safety (DVPS) so that a specific reviewer is responsible for a particular product for its first years on the market, allowing one reviewer to monitor it closely. For recently marketed products, CVM focuses on the medical review and causality assessment of individual case reports to identify possible safety concerns.

As part of the review process, reported signs are coded and/or verified and edited as appropriate. Clinical sign coding is accomplished using the Veterinary Medical Dictionary for Drug Regulatory Authorities (VeDDRA)(EMA, 2011). The VeDDRA dictionary has a hierarchical coding schema, from the System Organ Class (SOC) down to the High Level Term (HLT), Preferred Term (PT), and Low Level Term (LLT). This allows searching for groups of signs at a more or less specific level.

Regarding causality assessment, CVM uses the Modified Kramer algorithm to weigh the possible relatedness of an adverse event to the product administered according to a set of criteria. Each clinical sign in the report is evaluated by use of this algorithm and assigned a numerical causality score, which corresponds to categories such as "unlikely", "possibly", or "probably" drug related (Kramer et al., 1979). Causality assessment methods utilizing algorithms can help to provide a more structured and consistent approach to the assessments. Due to the high volume of ADE reports submitted, CVM cannot always assess each individual report for causality. Causality assessments are generally performed on the clinical signs in ADE reports for recently approved products, and on reports that contribute to a detected safety signal under investigation (see Section Signal Detection at CVM). An alternative system, the ABON algorithm, gives an overall qualitative score to the entire adverse event report, rather than each clinical sign. The ABON system is used by the European Medicines Agency (EMA) as well as some pharmaceutical companies for causality assessment (EMA, 2004). Both causality scoring systems take into account the association in time between product administration and onset of the clinical sign, dechallenge and rechallenge with the product if this occurred, previous association of the product with the type of adverse event reported, dose relatedness, and presence or absence of an alternative etiological candidate, among other information, including whether or not there is enough information to assess the reaction.

Signal Detection at CVM

A safety signal is defined by the World Health Organization as "reported information on a possible causal relationship between an adverse event and a drug, the relationship being unknown or incompletely documented previously"(WHO, 2015). With the large volume of data CVM receives annually, safety reviewers cannot always review the reports individually. Accordingly, data mining strategies, which involve the use of computer algorithms to analyze data in large complex databases, are being employed at CVM to more efficiently identify safety signals. These methods do not replace hands-on clinical review of the case reports that generated the signal and assessment of those cases to determine the medical implications of the signal. Signals that are detected are essentially hypotheses, not causal associations, and they need to be confirmed by case series examination. These measures assist in detecting signals in large volumes of data, helping to focus time and resources.

Understanding the case series concept starts with the recognition that the ADE database provides a source of observational data for a large/diverse population. This information is used to develop a case series, which is a summary of descriptive clinical information that can be used to help characterize the drug's safety profile and identify potential risk factors associated with certain adverse events. The FDA CDER/CBER Guidance for Industry, *Good Pharmacovigilance Practices and Pharmacoepidemiologic Assessment*, provides a detailed discussion of this concept (FDA, 2005).

A CVM case series commonly includes an analysis of the following:

- the clinical and laboratory manifestations and course of the event;
- demographic characteristics of patients with events (e.g., age, breed, sex);
- exposure duration;
- time from initiation of product exposure to the adverse event;
- doses used in cases, including labeled doses, greater than labeled doses, and overdoses;
- use of concomitant medications;
- presence of comorbid conditions, particularly those known to cause the adverse event, such as underlying hepatic or renal impairment.

This guidance also includes useful information about the principles of pharmacoepidemiological assessments and factors that are typically included in causality assessments, many of which also apply to veterinary pharmacovigilance programs. Spontaneously reported data is prone to numerous biases, most important being reporting bias. A new drug with greater publicity tends to generate more reports than older counterparts (Weber, 1984). Media attention to any reported problems tend to generate more reports. Underreporting occurs as well and, in general, reporting varies over time. Some factors that may affect reporting include the severity of the reaction and the length of time the product has been marketed. Confounding can also be a problem, by concomitant products administered, by concomitant medical conditions, or by product indication. This is why individual case series review of an identified signal is very important. The quality of the ADE reports is also critical for appropriate evaluation of these potential signals. Good case reports include a detailed description of the adverse event, including time to onset of signs, concomitant drugs or other products administered (including supplements and vaccines), concurrent medical conditions, patient signalment, clinical course of the adverse event, diagnostic results and therapeutic measures, information about dechallenge and rechallenge, and patient outcome. Also, good-quality case reports include complete information about the suspect product involved, including the trade name and established name of the drug, dosage form and strength, concentration, route of administration, and lot number. For medication error reports, case reports may include information about the type of error, type of personnel involved with the error, work environment in which the error occurred, and other possible contributing factors.

If a safety signal is identified during the ADE review process, a medical review and causality assessment of the case reports generating the signal is completed. For more recently approved products, part of this process is to perform a data review, which includes a list of clinical signs for a particular product in decreasing order of their reporting frequency. The clinical sign profile that is seen postapproval is compared with the labeled adverse reactions for the product, and the development of a Postapproval Experience (PAE) section may be proposed for addition to the drug labeling. Generally, a reviewer considers both the frequency and severity of signs for PAE section development, but a specific frequency threshold is not used to determine inclusion in the PAE section. A list of potential signs for inclusion is developed for consideration. For products that already have a PAE section as part of their labeling, new signs may be added as the result of signal detection and case series analysis. Signs that are being considered for addition to a PAE section are presented to the Monitored Adverse Reaction Committee (MARC) meeting. The MARC meeting is an interactive cross-CVM pharmacovigilance forum and is held on a regularly scheduled basis. The group consists of CVM veterinarians and other scientists, who work predominantly in the CVM Office of Surveillance and Compliance and the Office of New Animal Drug Evaluation (both post and preapproval areas of the Center). During the MARC meeting, safety reviewers present the case series information they have developed and the supporting pharmacovigilance data regarding the safety signal(s) of interest. Furthermore, they participate in discussions to reach a consensus regarding the development of appropriate label revisions and Center risk management responses. In addition, pharmacology overviews of recently approved products are presented to the MARC meeting attendees by the Office of New Animal Drug Evaluation (ONADE) scientific review staff so that safety reviewers can become more familiar with the safety and effectiveness profile of new products before they are marketed.

Communication of Drug Safety Information and Regulatory Intervention

CVM's pharmacovigilance efforts contribute to the following:

- Label revisions – PAE sections, warnings, formulation changes, product packaging
- Dear Doctor letters
- Client Information Sheets (CIS)
- Responses to Freedom of Information (FOIA) requests
- Postapproval risk management programs
- Journal articles
- CVM Updates (website) and other public communications.

Communication of Drug Safety Information

The labeling of an approved animal drug product is the primary source of information about the drug, including directions for safe and effective use, contraindications, warnings, precautions, and adverse reactions. The drug labeling is evaluated as part of the preapproval process to ensure that it is scientifically accurate and provides clear instructions to veterinarians for prescription drugs and to consumers for over-the-counter animal drugs. Label revisions may become necessary after the product has been marketed and used in a large and diverse population of animals. As discussed in Section Signal Detection at CVM, addition of a PAE section to the labeling serves the important purpose of completing the drug's safety profile. Dear Doctor Letters are letters drafted by drug manufacturers and sent to veterinarians in order to notify them of important new safety information discovered after a product has been introduced to the market. This information may include any new warnings, other safety information, or other important changes to the prescribing information of a drug product. Dear Doctor Letters are often issued by the company in conjunction with label changes, although not all labeling changes result in such a letter. Dear Doctor Letters issued since 2000 are posted on CVM's web site (FDA, 2011).

For some prescription animal drugs that may pose a serious and significant risk to the health of the animals being treated or to the humans handling the animal or the drug, the FDA may require sponsors to provide additional labeling, such as a Client Information Sheet (CIS) (FDA, 2017k). These information sheets are intended for distribution by the veterinarian to the client at the time of prescribing or dispensing of the drug. Some circumstances in which a CIS may be needed for a prescription animal drug include, but are not limited to: a drug with a narrow margin of safety; a drug that may cause adverse reactions that would necessitate prompt attention; a drug that has unusual or complicated dosing instructions; or a drug with user safety issues. An example of Client Information Sheets required for a specific drug class is that for the nonsteroidal antiinflammatory drugs (NSAIDs).

CVM utilizes its web site to disseminate information about adverse drug experiences and important announcements regarding animal drug product safety. One section of the web site, "CVM Updates", contains brief press releases issued by the Center for Veterinary Medicine on developments of interest to stakeholders and the public. CVM Updates may relate to any topic, but are often used to convey information about drug safety issues.

CVM is planning to publish the Center's adverse event data on the openFDA web site (FDA, 2017). Other information and reports from the ADE database can be requested on an individual basis by filing a Freedom of Information request (FDA, 2017m). CVM scientists may also disseminate new drug safety information through publications in professional journals and presentations at professional meetings.

Safety Measures Beyond Labeling

Additional risk mitigation strategies may at times be necessary to increase the safe and effective use of animal drugs. These may include methods of communication about drug safety information as described above (changes in labeling, issuance of "Dear Doctor" letters, drug name or packaging changes), as well as other types of measures such as restricted use or distribution of a drug, or, rarely, withdrawal of a medical product from the market. Two types of special postapproval surveillance programs are Postapproval Monitoring Programs (PAMPs) and Risk Minimization Action Plans (RiskMAPs). PAMPs may include specific postmarketing study commitments which are agreed to by a drug sponsor, and are conducted after FDA has approved a product for marketing. Postmarketing study commitments are currently conducted much more commonly for human drugs and biologics, as only a few postmarketing studies for animal drugs have been conducted at this time (e.g., sometribove zinc suspension, ractopamine). A RiskMAP is a strategic safety program designed to meet specific goals and objectives in minimizing known risks of a product while preserving its benefits.

Other Surveillance Methods

Though CVM was exempt from the Sentinel Initiative, other FDA centers were tasked to establish an active postmarket risk management system. With that understanding, Sentinel's goal is to develop a national electronic safety monitoring system comprised of active surveillance methodologies related to safety signal detection, strengthening, and validation. Access to existing electronic health-care databases is critical to the Sentinel Initiative.

An important concept is that Sentinel will augment but not replace existing postapproval surveillance systems. The potential capabilities of Sentinel are impressive in that they are focused on identifying and evaluating safety issues near real time, enhancing FDA's ability to evaluate safety issues not easily evaluated with the passive surveillance systems currently in place.

Although CVM was exempt from the Sentinel Initiative, the use of sentinel surveillance methods are of interest in the field of veterinary pharmacovigilance. CVM completed a project investigating the current electronic data sources that exist in the field of veterinary medicine. The project report, *Evaluation of Potential Data Sources for Animal Drugs Used in Veterinary Medicine*, can be found online (FDA, 2017n). The scope of the project was the identification, description, and evaluation of potential data sources and/or data environments for veterinary medicine. The following elements were considered in the project:

- utility for postmarket surveillance of FDA-regulated animal drugs;
- scope, content, structure, quality, and timeliness of data;
- availability, experience, and interest of investigators with knowledge of the data in using it for postmarketing product safety surveillance as well as plans for further data source enhancements;
- barriers that exist to including each data source in the Sentinel Initiative.

Of the data sources examined, only one was designed specifically for the primary purpose of researching animal health status, diseases, and the effectiveness of veterinary medical treatments. A key finding of the project was that for postapproval surveillance to be conducted as envisioned by the Sentinel System, animal health databases would only be useful if a link can be demonstrated between the drug, the animal to which it was administered, and the animal's health status after drug administration.

CVM's International Pharmacovigilance Efforts

CVM is actively involved in international pharmacovigilance activities through its participation in the VICH program. VICH is a trilateral program concerned with developing harmonized technical requirements for the approval of veterinary medical products (drugs and biologics) in the European Union, Japan, and the United States, and includes input from regulatory and industry representatives. Canada, Australia, and New Zealand participate as active observers. The VICH program was officially developed in April 1996 and has the following full title: International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products.

Conclusion

The success and benefit of any pharmacovigilance system requires the constant vigilance and cooperation of all stakeholders – veterinarians, industry, academia, animal owners, and state and federal government agencies. During product development, it is not possible to identify all safety concerns. Once a product is marketed, there is generally a large increase in the number of animals exposed to the product, including those with comorbid conditions and those being treated with concomitant medical products. Therefore, postmarketing adverse event data collection and safety evaluation based on observational data is critical for evaluating and characterizing a product's safety profile and for making informed decisions on risk management. The veterinary profession and animal patients ultimately benefit from the communication of adverse drug experience information that is evaluated by CVM.

Dosage Forms And Veterinary Feed Directives

Geof Smith and Jim E. Riviere

One of the primary differences between human and veterinary pharmacology is the wide range of dosage forms available to the veterinarian that occurs as a direct consequence of significant differences in the way drugs are administered to animals and humans. These differences are a consequence of obvious dissimilarity in anatomy and physiology, but also are a direct consequence of variations in behavior, husbandry practices, and inability to verbally communicate with animal versus human patients. In addition, some animals are raised for food production and thus drug delivery strategies that result in injection-site residues may not be acceptable solely due to possible human consumption of the delivery device or its residues. Different dosage forms are employed for four main reasons: ease of administration and thus compliance, controlled rate of drug delivery, ability to minimize meat or milk withholding times, and husbandry constraints in treating populations of animals in a production environment. The focus of this chapter is to introduce the reader to the wide variety of dosage forms encountered in veterinary medicine. Specifics on most of these formulations can be found in the individual therapeutic chapters or the introductory chapters on pharmacokinetics and drug absorption, distribution, metabolism, and excretion.

Pharmacokinetic Considerations and Controlled-Drug Delivery

By far, the dosage form has the greatest influence on the rate and extent of absorption of drugs. The physiology behind these factors is discussed in Chapter 2, their resulting effects on a drug's plasma concentration-time profile are presented in Chapter 3, and pharmaceutical aspects in Chapter 5. The development and impact of these formulations has been extensively reviewed elsewhere (Hardee and Baggot, 1998; Baggot, 2002; Martinez et al., 2002). When the absorption characteristics of a drug's formulation become rate limiting, and flip-flop pharmacokinetics becomes operative, the shape of the drug's concentration–time profile, and thus pharmacological effect, is in control of the formulation and not the animal's ability to clear the drug. In addition, innovations in drug delivery allow existing drugs to be more effectively used and provide extension of the commercial life of the product for a manufacturer.

The classic example of the effect of formulation is seen with the plasma concentration–time profiles of potassium, procaine, and benzathine penicillin G (Figure 59.1). The formulation strategy is to complex the active drug (e.g., penicillin G) with a moiety that delays its release to the surrounding capillary beds by modulating the drug's solubility. A pharmaceutics text should be consulted for the chemistry of these processes. The result is that the rate of release of the compound from the dosing formulation becomes slower than that of the drug's elimination, making it rate limiting.

The potential problems with these strategies are twofold. If one considers antimicrobial therapy for bacteria with very high therapeutic thresholds (e.g., minimum inhibitory concentrations, MICs), the prolonged-release formulations may never provide effective therapeutic drug concentrations. Second, such so-called "depot" preparations in food animals may result in persistent drug concentrations in tissues, thereby prolonging the withdrawal time. Drug depots at injection sites may persist much longer than effective blood concentrations and may be easily detected at slaughter. One must exhibit care to differentiate drug tissue concentrations at injection sites from those achieved after absorption and systemic distribution (Sanquer et al., 2006).

This scenario also nicely illustrates the reason that knowledge of both the extent and rate of drug absorption are needed to adequately describe the absorption of a drug and underscores why determination of drug bioequivalence (e.g., dosage form interchangeability) requires assessing both metrics related to rate (peak, time to peak) and extent (AUC) of drug absorption. The importance of these factors was also discussed in Chapter 3 under dosage regimen construction.

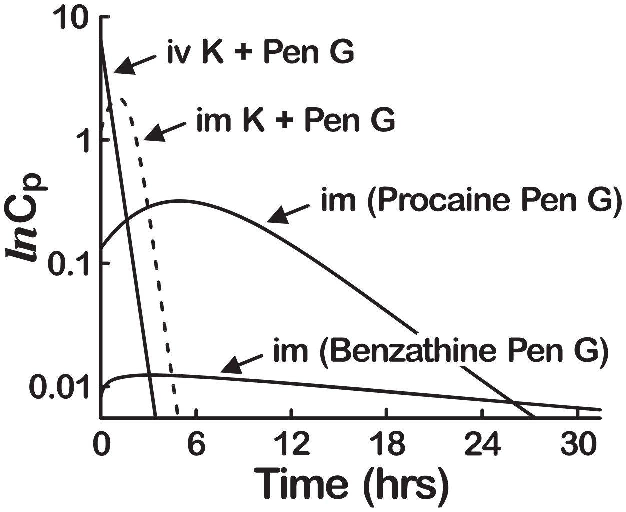

Figure 59.1 Effects of formulation and route of administration on the plasma concentration versus time profiles of penicillin G.

Approved dosages are very dependent upon the formulation of the drug utilized, a factor that must be considered when using any drug in a veterinary patient. This approach has recently been taken advantage of to develop other once-daily dosing of drugs such as antibiotics in veterinary species, the increased dosing interval being due either to the use of drugs with inherently long half-lives or depot release characteristics. These formulations stress the necessity of knowing the dosage form used when conducting any pharmacokinetic analysis as it may modulate the rate-controlling factor in drug disposition. In many cases, this can be detected only from intravenous pharmacokinetic experiments.

The development of depot preparations has received a great deal of attention by pharmaceutical industries. Some contraceptives in humans achieve monthly dosing intervals through injection in the subcutaneous tissue of insoluble tablets, which results in very slow drug release; the best example is the use of levonorgestrel implanted capsules (Norplant®). Similar strategies have been employed in veterinary medicine for the administration of growth promotants. These include estradiol formulated in rubber implants (Compudose®), progesterone and estradiol pellets (Synovex®), and zeranol (Ralgro®). Newer approaches include use of biodegradable gels that may be injected as a liquid through a syringe; these gels form a slowly degrading solid once in the tissue. Temperature-sensitive thermogels can also be used to control release of drug once in the body at physiological temperatures. A great deal of new technology is being developed for such formulations that promises more sophisticated dosage forms in the future. These approaches are fully discussed in Chapter 5.

Oral drug dosage forms achieve control of release through modulation of the surface area of dissolving drug particles, through the size of particles that alter their gastrointestinal transit time, or through the use of multiple layers in the formulation that control the rate and extent of drug release and dissolution. The simplest example is to coat a drug to prevent its dissolution in the acid environment of the stomach. These formulations are specifically designed for specific species, due to differences in gastrointestinal content and motility, as well as issues that include palatability. Capsules can be designed that initially release a bolus of readily soluble drug that functions as a loading dose into the animal. This is then followed by slower release of drug that maintains effective levels. For some compounds, only local delivery is needed to the gastrointestinal tract (e.g., certain antiparasitics), and the formulation can be designed for such activity. One recent example of this is the anthelmintic eprinomectin, which has been released in an extended therapy formulation (LongRange®) that maintains therapeutic plasma concentrations for more than 100 days. Work has occurred to specifically deliver drug to the colon in humans for localized effect. Again, it must be stressed that many of these controlled-release dosage formulations are specifically designed for species-specific anatomical (size of pyloris), biochemical (cellulose based for nonruminants), and/or physiological (pH, transit time) factors that prevent easy use in other species.

A truly unique aspect of dosage form not seen in human medicine are those employed in ruminants that take advantage of the observation that heavy materials sink in the rumen and are not passed further along the digestive tract. This has resulted in the design of mechanical dosage devices that infuse drug into the rumen for specific durations. For example a monensin controlled-release capsule is available that consists of a plastic capsule equipped with retaining wings to prevent the bolus from passing into the reticulum. The bolus sits in the rumen for an extended period of time, releasing monensin from one end for up to 100 days. Finally, slow-release osmotic pumps may be implanted in animals to achieve controlled drug infusions.

A major variable concerning parenteral injections relates to the physiology of the injection site. For a drug to be adequately absorbed from a depot preparation, there must be access to the perfusing capillaries and an adequate rate of tissue perfusion. A major source of variability is the muscle into which intramuscular injections are made. Studies have elegantly demonstrated in horses that if the injection is made between the fascial tissue bundles of a muscle group, less systemic absorption will occur than if the injection is in the muscle mass. Similarly, if the muscle group, or more likely, the SC injection site, has poor blood perfusion, less absorption may occur. If the injection results in a local tissue reaction, subsequent inflammation and fibrosis may "wall off" the drug formulation preventing absorption. Changes in ambient temperature, with compensatory changes in skin blood perfusion, may modulate absorption rate. There are numerous variables in these processes, and it is often only through the use of careful pharmacokinetic analyses that their influence on drug absorption cause can be ascertained.

Topical dosage forms include gels and patches that control diffusion from the dosage form to be rate limiting for dermal absorption. These products have been discussed in Chapter 2 and are fully reviewed elsewhere (Riviere and Papich, 2001). The advantage of dermal over oral or parenteral controlled-released approaches is that the topical gel or patch can be removed should cessation of dosing be required. Transdermal fentanyl patches for analgesia in dogs has been a particularly successful story using human patches. However, these cannot be easily transferred between species as the rate-limiting barrier may be species- and site-specific. As of this time, specific patches for animals have not been marketed.

In contrast, there are numerous topical spot-on, pour-on, collars, dip, and shampoo formulations for topical pesticides, often focusing on flea control. Some of these have resulted in once-monthly dose administration and increased owner compliance. These preparations are fully covered in Chapters 43 and 47 of the present text. In addition to these unique pour-on applications, large-animal veterinary medicine also employs ear-tags and dust-bags that allow topical drug delivery in cattle and swine in a rate- and dose-controlled fashion. Topical administration of drugs is now being expanded beyond ectoparasiticides as a novel formulation of flunixin has been developed for transdermal use in horses and cattle (Finadyne® Transdermal). The product has a longer duration of activity as compared to IV formulations of flunixin and maintains therapeutic concentrations for a greater length of time.

Palatability and Ease Of Drug Administration

Another factor important to veterinary medicine relates to the ease of drug administration to animals that might present danger to the individual administering the drug. This has resulted in formulating drugs in dosage vehicles that are palatable and will be easily eaten by the animal, but made of ingredients that do not alter drug absorption properties. A great deal of information is available from the pet food and vitamin industry that provides quantitative approaches to assess factors such as taste preferences and palatability (Ahmed and Kasrarian, 2002; Thombre, 2004). This has resulted in the development of chewable drug formulations as well as flavor ingredients that mask bitter taste or odors that animals refuse to eat. In contrast to human medicine, where sight and verbal cues may allow administering distasteful drugs to adults, animals rely on senses of taste and smell to determine whether a drug-containing formulation will be consumed. Other approaches to oral drug administration under consideration include use of dissolvable films and oral sprays for targeting the buccal cavity of patients. These are particularly being developed for cats where owners often have difficulty in administering other oral drug formulations.

A final approach that is relatively unique to veterinary medicine includes the direct administration of drug into drinking water, into lick-tanks, or on feed for use in large production settings (e.g., cattle, swine, poultry). An important distinction with this continuous form of drug administration is that, unlike the bolus effect seen with individual liquid dosing or rapidly dissolving tablets, absorption may not be first-order (Mason et al., 2009). If administration is constant in water or feed, absorption may be zero-order and have pharmacokinetic behavior resembling an infusion. Finally, drugs may be administered in medicated blocks, which results in ease of administration but little control of individual animal dosage.

Veterinary Feed Additives

One strategy for administering drugs to animals that is unique to veterinary medicine is oral dosing via feed. This is often necessary due to the need to treat a large number of animals in a production environment. Unlike individual animal dosing, this approach does not assure that a specific dose of drug reaches each animal, since drug dosage is now a function of food consumption. As mentioned above, issues of palatability and odor also must be taken into consideration.

The legal control of feed additives is also different than other drug formulations. The Veterinary Feed Directive (VFD) refers to a relatively new category of medicated feeds created by the Animal Drug Availability Act of 1996. Prior to this time, the Food and Drug Administration (FDA) had only two options for regulating the distribution of animal drugs: over-the-counter or prescription. The primary purpose of the VFD was to provide an alternative to these categories for certain therapeutic drugs that are mixed in feed. A VFD drug still ensures the participation of a veterinarian, but it allows producers to acquire medicated feeds through traditional manufacturers without involving a pharmacist or having to follow state pharmacy laws.

In 1996, the Center for Veterinary Medicine (CVM) of the FDA expressed a greater need for control over the use of certain antimicrobial agents in medicated feeds. Initially, it was suggested to mandate all new therapeutic agents approved for use in feed be for use by prescription only. However, having additive drugs approved as prescription-only was unacceptable to the animal agriculture and feed industry. Requiring these drugs to be for use by prescription only would have turned feed mills into drug stores because they would be forced to mix a new batch of feed each time a prescription was written. Studies done by the American Feed Industry Association (AFIA) in the 1990s estimated the average feed costs in the swine industry would have risen from $36 to $100 per ton because of additional costs associated with special ordering and the need to mix only small volumes of feed at once. These prescription drugs would also fall under the direction of most state pharmacy regulations, which would further complicate the ability to manufacture and distribute medicated feed.

The VFD was therefore created to be an alternative to the traditional prescription classification. It places a much greater emphasis on professional control as compared to over-the-counter medications while still allowing agricultural producers to obtain medicated feeds efficiently and cost effectively. In 2014 the FDA published Guidance 213 to limit the use of feed and water antibiotics in food animals to “uses that include veterinary oversight or consultation.” Therefore beginning in 2017, all approved feed grade antibiotics used in food animal production require VFD approval prior to use. Over the counter feed or water medications have been phased out as well as label indications that would be considered non-therapeutic (for example using antibiotics to promote feed efficiency). As with other medicated feeds, the extralabel use of any VFD drugs is prohibited. The lone exception to the above rule are ionophores such as monensin or lasalocid which are not considered “medically important antibiotics.” Chapter 55 should also be consulted for further discussion of drug regulations.

The initial requirement for using a VFD medicated feed is a valid veterinarian-client-patient relationship. As defined by the American Veterinary Medical Association (AVMA), this relationship exists when:

1) The veterinarian has the responsibility for making medical judgment regarding the health of the animal(s) and the need for medical treatment, and the client has agreed to follow the instructions of the veterinarian.
2) There is sufficient knowledge of the animal(s) by the veterinarian to initiate at least a general or preliminary diagnosis of the medical condition of the animal(s). This means the veterinarian has recently seen and is personally acquainted with the keeping and care of all the animal(s), and/or by medically appropriate and timely visits to the premises where the animals are kept.
3) The practicing veterinarian is readily available, or has arranged for emergency coverage, for follow-up in case of adverse reactions or failure of the therapeutic regimen to solve the problem.

Once a veterinarian has made an initial diagnosis, he/she can issue a signed VFD on a preprinted, multipart form. The veterinarian gives the form to the producer, who then orders the medicated feed from the feed supplier. A VFD feed may not be distributed to a producer without a signed VFD form. Three groups are involved:

1) The person or firm supplying a VFD drug to a producer must receive and retain a copy of the signed VFD form issued by the veterinarian.
2) Licensed feed manufacturers and distributors who ship VFD feed to a downstream distributor or retailer for inventory must receive and retain a copy of written acknowledgement stating that the VFD feed will be further distributed only in accordance with FDA requirements.
3) All distributors and retailers who do not hold a feed mill license must notify the FDA within 30 days of their initial VFD feed shipment.

The form for Veterinary Feed Directive products should be provided to the veterinarian by the manufacturer of the specific therapeutic agent (Figure 59.2). This form must be completed by the veterinarian and should normally include the following information:

1) the name, address, and telephone number of the producer;
2) the species, location, number of, and description of animals being treated;
3) the date(s) of treatment (if different from the date on the VFD form);
4) the name of the drug to be used, the concentration of the drug to be included in the feed, and the amount of feed to be manufactured;
5) the directions for mixing and feeding (including dilution) and duration of treatment, including appropriate withdrawal times; the expiration date of the feed;
6) the veterinarian’s name, address, license number, state of licensing, and signature.

The form is the most significant component of using VFD approved medications. A VFD order cannot be issued by telephone. If the form cannot be hand-delivered, it can be faxed or sent via an email attachment; however, the original form must be received by the distributor within 5 working days. VFD forms have to be retained for a minimum of 2 years by all three parties involved (the veterinarian, the producer, and the feed mill) and should be available for review by the FDA.

Only vendors with a valid feed mill license are authorized to store VFD products, which means that a producer is not allowed to keep a surplus of medicated feed

on the farm. However, licensed veterinarians are allowed to act as distributors of VFD feeds by notifying the FDA once, in writing, 30 days before the first anticipated distribution of medicated feed. More information on VFD regulation can be find in the FDA Guidance for Industry 120 document available at the FDA website: www.fda.gov/downloads/AnimalVeterinary/GuidanceComplianceEnforcement/GuidanceforIndustry/UCM052660.pdf.

As VFDs become more common the above process may change. Plans and resources for electronically generated VFD forms are currently underway but have not been fully developed. Companies such as GlboalVetLink are working to develop programs by which computer generated VFD forms could by written by veterinarians and distributed to both the client and feedmill with copies automatically saved on a database for an extended period of time. Certainly, the coming years will see a significant expansion in the use of VFD drug across all major food animal species.

Site-Directed Therapy

The final consideration related to veterinary dosage forms are those drugs specifically designed for local effects. These include intramammary and intrauterine formulations, and ophthalmic and otic drugs. Examples of these are discussed under the individual drug sections and special therapy chapters of this text.

Evidence-Based Pharmacotherapy

Ronette Gehring

Introduction

Evidence-based veterinary medicine (EBVM) is a formal approach to integrating the best research evidence with clinical expertise and client perspectives to provide high-quality veterinary services. This chapter will focus on the application of EBVM principles to pharmacotherapy (the selection of pharmacological treatments and dosage regimens). The EBVM approach guides the busy practitioner through the massive amount of constantly and rapidly evolving scientific data, so that he/she can make the best clinical decisions possible by focusing on information that is directly related to specific patient problems (Cockcroft and Holmes, 2003).

How is EBVM Different from Other Approaches to Pharmacotherapy?

It seems obvious that treatment choices should be based on the best available evidence, but many approaches to clinical practice can result in biased or incomplete assessment of available options. These approaches include, but are not limited to, relying on standardized protocols, perusing the information about drugs that is provided by pharmaceutical companies, basing decisions on pathophysiological rationale or unsystematic clinical observations of previous cases, seeking advice from colleagues and experts, and performing unstructured appraisals of information in textbooks, journals, and online resources. Personal experience is subjective and can be misleading, predictions based on pathophysiological rationale need to be validated with randomized controlled clinical trials, and evidence from the scientific literature needs to be systematically evaluated to identify poorly designed studies, poor-quality data, or biased analyses.

EBVM sets itself apart from other approaches to clinical practice in that it emphasizes the systematic review of all available evidence. Randomized controlled clinical trials reported in the scientific literature are the preferred evidence, but, if these do not exist, evidence from expert opinion, case reports, personal experience, and other nonliterature-based sources can be considered. Regardless of the source, all evidence needs to be collated, assessed, and ranked to support objective decisions regarding the treatment of patients.

How is EBVM Applied to Selecting the Best Treatment for a Specific Patient?

EBVM can be defined as “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients” (Sackett et al., 2000). This means that clinicians should follow an explicit and methodical approach to their clinical decision making so that they can explain how and why one treatment option was chosen over another. There are three foundational skills that are required to do this:

1) Be able to identify information needs and transform them into questions.
2) Know where to seek the evidence needed to answer these questions.
3) Be able to understand and critically appraise (judge the quality) all the evidence.

Transforming Information Needs into Questions

One of the key skills for applying the EBVM approach to clinical practice is translating information needs that arise from a clinical scenario into questions that can guide the search for evidence. The following are some examples of clinical questions that are focused on pharmacotherapy:

1) Is drug X effective for treating condition Y?
2) Is the efficacy of drug X worth the harm (adverse effects) it causes in treating condition Y?
3) Is the efficacy of drug X worth the cost of treatment for condition Y? (i.e., Is drug X an efficient way to treat condition Y?)

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.
© 2018 John Wiley & Sons, Inc. Published 2018 by John Wiley & Sons, Inc.
Companion Website: www.wiley.com/go/riviere/pharmacology

4) How exactly should drug X be used in treating condition Y?
5) What is the place of drug X in the therapy for condition Y?
6) Can drug X cause problem Y?
7) What other drugs may be helpful in a patient who has not responded to drugs X, Y, and Z for condition B?
8) What is the expected outcome of drug X?

Once the question has been formulated, appropriate search terms can be identified to ensure that a search of the scientific literature and other information sources is productive and thorough, producing relevant results.

Finding Evidence to Answer the Questions

Traditional sources of information for practicing veterinarians include student and course notes, print journals, and textbooks. These may all be valid sources, depending on the clinician's needs, but the disadvantage is that they can quickly become outdated and/or are costly to access and update. More recently, the Internet and electronic media have become relatively inexpensive and convenient sources of scientific information, making it possible to access the scientific literature without going to a physical veterinary library. In addition, information on the Internet or an electronic resource is easier to update compared to its printed counterpart, and is easy to search. This can, however, produce a glut of information about any particular subject, requiring a lot of effort to sift through and discern its relevance, quality, and validity. Despite this disadvantage, a survey conducted by the American Veterinary Medical Association in 2008 found that 88% of veterinarians thought that the Internet enhanced their access to the latest scientific information and research (AVMA, 2008).

A survey conducted in 1996 found that medical doctors often had the need for more information about treatments and drugs during consultations, but searching for information was time consuming. Also, the available information could be overwhelming and difficult to evaluate (Smith, 1996). Veterinarians probably face similar challenges. Ideal information sources would therefore be directly relevant to the veterinarian's practice, valid, and require minimal time and effort to access (Shaughnessy et al., 1994). Based on this assumption, highly useful types of information would be regularly updated, evidence-based electronic textbooks, systematic journal reviews, portable summaries of systematic reviews, and online Internet reviews. Print media seems less useful as it is more difficult access, and primary sources (e.g., journal articles) require time and effort to collate and critically appraise for validity.

Since the conduct of these surveys, more high-quality online veterinary medical information resources have become available. Links to these resources can be found on the website of the Evidence-Based Veterinary Medical Association (EBVMA), a community dedicated to evidence-based veterinary medicine based in the United States (https://ebvma.org). Resources focused on veterinary drugs remain scarce, but there are growing databases of reviews of current best evidence to answer specific clinical questions (e.g., BestBETs for Vets, a project run by the Centre for Evidence-based Veterinary Medicine at the University of Nottingham, available at: http://bestbetsforvets.org). Evidence summaries of the literature pertaining to contentious label and extralabel use of drugs for species-specific indications are also available as part of the drug information monographs developed by the United States Pharmacopeia (USP). These monographs are no longer updated by the USP, but the historic documents are archived on the website of the American Academy of Veterinary Pharmacology and Therapeutics (AAVPT) (www.aavpt.org). The evidence summaries have been digitized into an online database to facilitate searching and updating and a link is also available at www.aavpt.org.

Appraising the Evidence

Once all the available information related to a clinical question has been gathered, it needs to be critically appraised for quality and validity, and weighted according to the statistical and methodological rigor of the studies that generated the data. Ideally, only data from the scientific literature should be considered, but this may not always be possible in veterinary medicine due to the scarcity of relevant clinical studies. Expert opinion, case reports, personal experience and other nonliterature-based sources can therefore also be considered, but need to be evaluated, ranked and weighted accordingly in the clinical decision-making process.

The classical evidence hierarchy is shown in Figure 60.1. In this classification, the systematic review is considered the pinnacle of evidence as it combines the results of different studies in a rigorous and systematic manner to best understand how the results of clinical studies represent reality. These are rare in veterinary medicine, particularly with regards to understanding the value of drugs for the treatment of specific conditions in different species.

A notable exception to the scarcity of EBVM resources in veterinary pharmacotherapeutics is the collection of Veterinary Drug Information Monographs originally published by the United States Pharmacopeia. The goal of developing these monographs was to create a comprehensive single source of veterinary information about a drug. The process incorporated evidence-based approaches with interpretation of the evidence by an

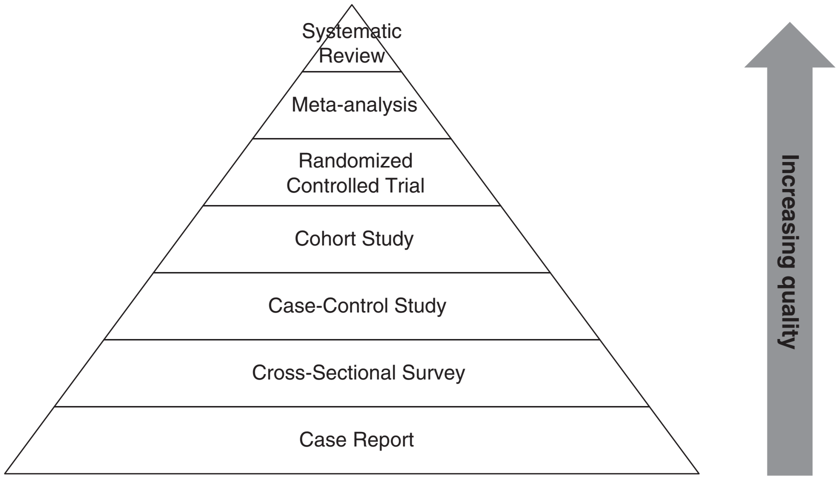

Figure 60.1 The evidence hierarchy.

Table 60.1 Evidence ratings

Evidence quality
A. Good evidence to support a recommendation for use
B. Moderate evidence to support a recommendation for use
C. Insufficient evidence to support a recommendation for use
D. Moderate evidence to support a recommendation against use
E. Good evidence to support a recommendation against use

Evidence type
1. Species-specific evidence from at least one large randomized and controlled trial (RCT) or multiple small RCTs
2. Species-specific evidence from a small RCT, disease models, large case studies, or pharmacokinetic studies using surrogate endpoints or evidence from well-designed trials in a different species that is considered appropriate for comparison
3. Dramatic results from either well-designed, species-specific trials without controls or small case studies
4. Pharmacokinetic studies without surrogate endpoints
5. In vitro studies
6. Opinions of respect authorities on the basis of clinical experience or reports of expert committees

expert committee (earlier editions of this textbook contain detailed descriptions of the process).

The indications section of these monographs was where the EBVM approach was most strongly applied. For all extralabel indications, and for any label indication that was viewed as contentious by a member of the expert committee, tables summarizing the evidence in support of that indication from the scientific literature were generated. Each table contained the citation information, the type of study (e.g., case report, clinical trial, disease model, in vitro study, metaanalysis, pharmacokinetic study with surrogate endpoints, pharmacokinetic study without surrogate endpoints), whether treatments were randomized, type of control used (e.g., positive, negative, uncontrolled), and the type of masking used (e.g., single-masked, double-masked, nonmasked). A synopsis of the methods used, doses and duration of therapy studied, results, author conclusions, and limitations noted by the USP staff were included. Indications were then classified as “Accepted”, “Potentially effective” or “Unaccepted”, and assigned an evidence rating based on the quantity and quality of evidence. The evidence rating consisted of a letter (A–E) and a number (1–6) as indicators of the evidence quality and type, respectively. The evidence rating system is summarized in Table 60.1.

Funds are no longer available for the development of new veterinary drug information monographs, nor are the existing ones being updated anymore. But they remain a unique resource, and offer a framework for the rigorous evaluation of available information for veterinary drugs. It is hoped that, in the future, resources will be found to continue this important work.

Chemical Residues In Tissues Of Food Animals

Jim E. Riviere

Most of this textbook has focused on describing the pharmacodynamics and pharmacokinetics of drugs in animals. In both human medical and companion-animal veterinary practice, the primary concern in drug selection and use is the therapeutic end point, whether or not the drug is efficacious against the disease being treated. Doses are usually administered at label recommendations, and, if greater than label doses are administered, only potential toxicity is of concern. While this line of reasoning is also true to a large degree in food-animal production, veterinarians and producers involved in the treatment of disease in food animals bear the additional concern of the persistence of drug residues in the edible tissues after the disease process has been treated. Adulteration of the food supply with antimicrobial agents, pesticides, environmental contaminants, and other chemicals has been a growing source of concern to the general public and special-interest groups in recent years.

The importance of chemical residues in the edible tissues of food-producing animals has been thoroughly reviewed elsewhere (Bevill, 1989; Sundlof, 1989; Van Dresser and Wilcke, 1989; Mercer, 1990; Riviere, 1991, 1992a; Kindred and Hubbert, 1993; Baynes et al., 2015) and has been the topic of a recent text by the author (Baynes and Riviere, 2014). The purpose of this chapter is to acquaint the veterinarian with the legal and regulatory issues concerning the control of drug and other chemical residues in the United States, and to review some of the pharmacokinetic parameters used to determine withdrawal times for drugs and other chemicals in food animals. Drug use in food animal practice is fully discussed in Chapter 52 and the legal regulations are also extensively covered in Chapter 55 of this text. All of these references should be consulted for an in depth analysis of this complex and ever changing topic.

The primary parameter used by veterinarians to prevent violative tissue residues is the length of the withdrawal time, or the time required for a drug after dosing to be depleted from the animal before the animal's meat can be marketed for human consumption. In dairy practice, this is the milk discard time. Recently, government regulation and control as well as adoption of more sensitive multiresidue analytical tools have necessitated more stringent adherence to withdrawal times, and on-site monitoring for many drugs has been instituted. This may have an economic impact on production costs. Unlike in previous editions of this text, withdrawal times will not be tabulated, because they are subject to constant regulatory revision. Extensive tables of tissue depletion pharmacokinetic data are published elsewhere (Craigmill et al., 2006). Current withdrawal times are provided on the Food Animal Residue Avoidance Databank (FARAD) website, available at: www.farad.org.

The Concern Over Residues in Food

A great deal of concern has been demonstrated over the last 50 years about the presence of chemical adulterants or residues, mainly antimicrobials and pesticides, in the meat, poultry, and milk supplies of the United States. By definition, a chemical residue is either the parent compound or metabolite of that parent compound that may accumulate, deposit, or otherwise be stored within the cells, tissues, organs, or edible products (e.g., milk, eggs) of an animal following its use to prevent, control, or treat animal disease, or to enhance production. Residues can also result from unintentional administration of drugs, or food additives. Finally, accidental exposure to chemicals in the environment can also result in tissue residues.

Concerns over food residues are economic as well as public health related. For example, the contamination of milk with antibiotics, most commonly penicillin, can affect starter cultures used to make fermented milk products such as cheeses, buttermilk, sour cream, etc., which can result in economic losses to those processors. From a public-health viewpoint, both the US government and producer associations have taken active roles in minimizing antibiotic residues in meats and milk. Penicillin, for example, is known to induce allergic reactions in some sensitive people, and therefore,

Veterinary Pharmacology and Therapeutics, Tenth Edition. Edited by Jim E. Riviere and Mark G. Papich.

Companion Website: www.wiley.com/go/riviere/pharmacology

penicillin-tainted milk poses a health risk for these individuals. Similarly, chloramphenicol has been reported to induce blood dyscrasias that may lead to death; hence, its use in food-producing animals has been prohibited by the Food and Drug Administration (FDA). The FDA has also prohibited the use of nitrofurans in food-producing animals (excluding the topical routes for administration) because studies have shown them to be carcinogenic. Not only therapeutic drugs but pesticides create residue problems. Most pesticides are administered topically, allowing some amount of percutaneous absorption and sequestration in edible tissues. Lindane has been detected in the fat deposits of sheep dipped in a 0.0125% lindane emulsion 12 weeks after topical exposure (Collett and Harrison, 1963). Other studies have shown lindane residues in sheep, goats (Jackson et al., 1959), and lactating cows (Oehler et al., 1969). In addition to lindane, many common pesticides (organochlorines, organophosphates, botanicals, pyrethrins, etc.) and herbicides used in agriculture today that are applied topically have been shown to produce residues in food-producing animals. Environmental contaminants (e.g., heavy metals, PCB, dioxins, mycotoxins) are also of major concern today. Tissue residue violations detected by governmental monitoring programs have been summarized by Sundlof (1989) as well as Baynes et al. (2015).

The USDA Food Safety and Inspection Service (FSIS) manages the National Residue Program (NRP) and yearly publishes sampling plans for the next year (Blue Book) and sampling results for the prior year (Red Book). Both public-health and economic concerns have been the major driving forces in the United States and in other countries behind the search for ways to minimize the threat of residue contamination of the public food supply. The latest editions of these reports (2014, 2015) have served as the source of some NRP details in the present chapter.

Contamination of the food supply with chemical residues is rarely an intentional act and usually results either from failure to observe the correct meat withdrawal or milk discard time for a drug after it has been used to treat a disease process in food animals or from accidental contamination of feed by chemicals or drugs. An early study by Van Dresser and Wilcke (1989) provides some interesting insight on drug residue problems in food-producing animals. In that study, streptomycin, penicillin, sulfamethazine, and oxytetracycline were the four most common antibiotics found in tissues, with sulfamethazine being the most commonly found sulfonamide in animal tissues. Long-acting formulations of these drugs (i.e., penicillin and oxytetracycline) had the highest association with violative residues in the animals involved in the study. Injectable drugs were more likely to be associated with residue problems than were feed additives and boluses. Most of these residues were found in veal calves, cows, and market barrows and gilts. The most frequently cited reason for violative residues was failure to observe the correct withdrawal time for the drug. Failure to observe the correct withdrawal time was cited as the most common reason for violative drug residue levels in a study performed by the FDA in the 1970s (Bevill, 1984) and continued to be the most common cause of residue violations in the 1990s. Interestingly, in this study the producer was found to be the responsible party in 80% of the cases investigated for violative levels of drug found in edible tissues (when the responsible party could be identified); unapproved drug use (extralabel drugs) is not considered a major cause of drug residues in animals. Ways to prevent drug residues will be discussed in Section Residue Prevention.

The FDA and Environmental Protection Agency (EPA) establish tolerances for a drug, pesticide, or other chemical in the relevant tissues of the food-producing animals. The tolerance is the tissue concentration below which a marker residue for the drug or chemical must fall in the target tissue before that animal's edible tissues(s) (meat, milk, or eggs) are considered safe for human consumption (Riviere, 1991). The marker residue may be the parent compound, or a metabolite, and reflects a known relationship to the total residues of the drug or chemical (parent and all metabolites), although this has recently been suggested to not be constant but instead sensitive to disease and other pathophysiological conditions seen in target animals (Lin et al., 2016). The target tissue is an edible tissue, frequently liver or kidney which, when the compound has depleted below the tolerance, assures that all edible tissues are safe for human consumption. Tolerances for different tissues are considered legal end points for which drug withdrawal times are established. Tolerances are established based on assessment of potential hazard of consumption to humans, a topic extensively reviewed elsewhere (Gehring et al., 2006; Baynes and Riviere, 2014). Oral toxicity studies are conducted in animals leading to the determination of an acceptable daily intake (ADI) for the compound in the human diet. These studies consider the compound's carcinogenic potential, systemic, reproductive, and developmental toxicity, and incorporate various safety factors. Recently, the potential for an antimicrobial compound to induce resistance in bacteria is also factored in. A safe concentration for human consumption is calculated using an equation that accounts for the amount of a specific food consumed by a person representing a high-consuming population (e.g., 19-year-old males) so that a safe concentration of the drug in this food (e.g., meat, milk, eggs) can be established. Various safety factors and statistical considerations are built into these determinations, and a tolerance for this drug in the specific tissue is established where appropriate and published. For example, safety factors reflect the duration of exposure and the nature of the toxic effects associated with the chemical. A teratogen requires a larger safety factor than a nonteratogen, and ADIs based on a short-term subchronic study use a larger safety factor than ADIs based on chronic studies. The tolerance is for a specific drug or chemical entity and reflects both the inherent toxicity of the chemical as well as assumptions about the human consumption of the tissue for which the tolerance is established. Tolerances are determined for the active ingredient (the drug substance or its metabolite) and are not established for the specific formulation of the commercial drug product. A full discussion of this process is presented in the latest FDA Guidance *General Principles for Evaluating the Human Food Safety of New Animal Drugs Used in Food-Producing Animals – July, 2016;* it has also been reviewed (Baynes et al., 1999; Baynes and Riviere, 2014) and can be found in toxicology or risk assessment texts. It is important for the veterinarian to realize that the end point for determining withdrawal times, the tolerance, is a combined scientific and legal concept and therefore is ultimately controlled by regulatory and not purely scientific and medical practices.

The actual withdrawal time appearing on a drug label is also a function of the experimental design that the manufacturer used in the research studies submitted to the FDA for approval. Thus, although the science governing the withdrawal time is based on the pharmacokinetic principles discussed below, the withdrawal time is actually determined based on experimental data. Generally, a drug is administered to healthy animals, groups of the animals are slaughtered at sequential time intervals, and their edible tissues are analyzed for drug concentrations. The withdrawal time is the time from cessation of treatment to the time it takes for the residues of the drug to deplete below the safe concentration. A statistical method (*statistical tolerance limit procedure*) is used to determine the time at which the marker residue depletes to the tolerance in the target tissue. The method determines the time, rounded up to the next whole day, at which the upper bound of the marker residue tissue concentration is below the established tolerance in the target tissue (where the upper bound is statistically determined to represent with 95% confidence the 99th percentile of the population). Withdrawal times for the FDA-approved drugs for use in food animals are only valid for the specified species, dose, route, and frequency of administration. They are also specific to the manufacturer's product and formulation; thus, a drug substance (the active ingredient) may have different withdrawal times when present in differently formulated drug products. An analogous process occurs in establishing milk discard times and in determining the withdrawal times for drugs administered to egg-laying poultry (although presently, all drugs approved in the USA for use in laying hens have a 0-day withdrawal).

Regulation of Drug Residues in Animals

Producers, veterinarians, and other persons involved with chemicals and food-animal production should be acquainted with a few terms and the agencies involved in drug residue control in order to better understand the drug residue problem and how withdrawal times are determined.

The use of drugs in veterinary medicine, especially in food-producing animals, is closely regulated in the United States by the FDA under the Department of Health and Human Services. The FDA is charged, through the Federal Food, Drug and Cosmetic Act, with regulating the use of drugs in humans and in animals as well as requiring that the safety and efficacy of a drug be established before the product can be approved for use in animals, including those drugs added to animal feeds. The FDA also regulates human biologics, medical devices, drugs, and food safety. The FDA's Center for Veterinary Medicine (FDA-CVM) is responsible for the regulation of drugs, medical devices, and feeds intended for animals. The FDA is charged with the responsibility for establishing withdrawal times for drugs and the tolerances of drugs. The FDA and the EPA share responsibility for establishing tolerances for pesticide residues in animal-derived foods.

Whereas the FDA establishes safety guidelines for drug use in food animals, it is the responsibility of the USDA to enforce the standards established by the FDA and the EPA. The USDA, through authorization by the Federal Meat Inspection Act and the Poultry Inspection Act, inspects meat and poultry for sale through interstate commerce. The USDA is also authorized to test the tissues of food-producing animals through provisions in the Federal Insecticide, Fungicide and Rodenticide Act to determine whether violative levels of residues of chemicals and drugs are present. The USDA FSIS monitors these tissues through the NRP and identifies problems with drug and chemical residues. The NRP has been in existence for over 30 years and has concentrated on individual as well as population sampling for monitoring and surveying possible residue problems in slaughter animals. In 1992, the NRP estimated they would collect some 350,000 specimens that year to analyze for antimicrobial and pesticide residues (Kindred and Hubbert, 1993). The FSIS is the largest safety inspection force in the federal government (Norcross and Post, 1990). A few years ago, FSIS introduced a new three-tiered monitoring plan and more sensitive multiresidue analytical methods. Sampling occurs in a random commodity-specific national plan, as well as at the production and herd level. The number of samples and selection criteria have changed in 2014–2015 and thus comparisons to previous data may be problematic.

There are a number of rapid screening test, once used by FSIS and in producer food safety programs. The FSIS has used several rapid tests for determining contamination of animal products. Among these are the Swab Test on Premises (STOP) for antibiotic and sulfonamide residues, the Overnight Rapid Beef Identification Test (ORBIT) for species identification of meat, the Calf Antibiotic and Sulfa Test (CAST), the Sulfa-on-Site (SOS), and a variety of enzyme-linked immunosorbant assays (ELISAs) (Norcross and Post, 1990). Milk in bulk tanks and from individual animals is assayed for antibiotic residues using various testing strategies: Penzyme III (SmithKline Beecham Animal Health), Spot Test (Cambridge Biotech Corp.), Charm Tests (Charm Sciences, Inc.), and Delvo tests (Gist-Brocades Food Ingredients, Inc.), to name only a few. This area is difficult to adequately summarize because rapid advances in analytical screening methodologies have led to the rapid development of new tests.

Other federal government agencies have defined roles in regulating the sale and use of drugs in animals, including the Drug Enforcement Agency (a division of the Department of Justice), the Animal and Plant Health Inspection Service (a part of the USDA), the EPA (mainly for pesticides), and the Department of Transportation. On a state level, the Department of Public Safety, Department of Health, the Animal Health Commission, Boards of Veterinary Medical Licensing, and Pharmacy Boards all have some regulatory influence over the use of drugs in food-producing as well as companion animals. Other legal jurisdictions, including the European Union, have established protocols that should be consulted for details in these countries. As in the USA, these regulations are fluid, end points change based on residue sampling results and new drug submissions. One should always consult the relevant government websites for the latest information.

The Veterinarian and Extralabel Drug Use

In the USA, the FDA approves new animal drugs for specific indications in a particular species or subclass of animals (e.g., dairy cattle, weanling pigs, etc.). Occasionally, veterinarians may encounter diseases or conditions in animals for which there are no FDA-approved drugs. Under such circumstances, US veterinarians often administer drugs that are not approved for use in food animals or they administer approved drugs in nonapproved ways, practices commonly referred to as “extralabel” usage. Extralabel drug use is defined as the use of a drug in a manner that is inconsistent with its FDA-approved labeling, a practice that, until 1994, was technically illegal. Recognizing that the Food, Drug and Cosmetic Act (FD&C) placed veterinarians in an untenable position of having to choose between providing for relief of animal suffering or complying with the law, the US Congress passed the Animal Medicinal Drug Use Clarification Act (AMDUCA) in 1994. AMDUCA amended the FD&C Act to allow veterinarians under specific conditions to prescribe and administer drugs in an extralabel manner. Table 61.1 lists drugs specifically prohibited from extralabel use in food animals. Under AMDUCA, veterinarians may resort to the extralabel use of approved animal and human pharmaceuticals provided that the following conditions are met:

1) There is no approved new animal drug that is labeled for the intended use and that contains the same active ingredient which is in the required dosage form and concentration, except where a veterinarian finds, within the context of a valid veterinarian–client–patient relationship, that the approved new animal drug is clinically ineffective for its intended use.
2) Prior to prescribing or dispensing an approved new animal or human drug for an extralabel use in food animals, the veterinarian must:
   - make a careful diagnosis and evaluation of the conditions for which the drug is to be used;
   - establish a substantially extended withdrawal period prior to marketing of milk, meat, eggs, or other edible products supported by appropriate scientific information, if applicable;
   - institute procedures to assure that the identity of the treated animal or animals is carefully maintained; and
   - take appropriate measures to assure that assigned timeframes for withdrawal are met and no illegal drug residues occur in any food-producing animal subjected to extralabel treatment.

The following additional conditions must be met for a permitted extralabel use in food-producing animals of an approved *human* drug, or of an animal drug approved only for use in animals not intended for human consumption:

1) Such use must be accomplished in accordance with an appropriate medical rationale.
2) If scientific information on the human food safety aspect of the use of the drug in food-producing animals is not available, the veterinarian must take appropriate measures to assure that the animal and its food products will not enter the human food supply.
3) Extralabel use of an approved human drug in a food-producing animal is not permitted if an animal drug approved for use in food-producing animals can be used in an extralabel manner for the particular use.

Implicit in these regulations are that the veterinarian makes every effort to first use an approved drug at an approved dosage, that an individual veterinarian–client–patient relationship exists between the producer

Table 61.1 Drugs prohibited from extralabel use (ELDU) in food animals. Source: Adapted from Food Animal Residue Avoidance Databank, 2016.

Drugs with no allowable extralabel uses in any food-producing animal species

- **Chloramphenicol**
- **Clenbuterol**
- **Diethylstilbesterol (Des)**
- **Fluoroquinolone-class antibiotics**
- **Glycopeptides**
  - all agents, including **Vancomycin**
- **Medicated feeds**
- **Nitroimidazoles**
  - all agents, including **dimetridazole**, **ipronidazole**, **metronidazole**
- **Nitrofurans**
  - all agents, including **furazolidine**, **nitrofurazone,** and others

Drugs with restricted extralabel uses in food-producing animal species

- **adamantane and neuraminidase inhibitors** in all poultry, including ducks
  - these agents are approved for treatment or prevention of influenza A
- **Cephalosporin-class antibiotics** ***except*** **cephapirin** in all classes of cattle, chickens, pigs, and turkeys
  - ELDU restrictions apply to all production classes of major food-animal species
    - no ELDU for purpose of disease prevention
    - no ELDU that involves unapproved dose, treatment duration, frequency, or administration route
    - agent must be approved for that species and production class
  - ELDU restrictions *do not apply* to minor-use food animal species
- **Gentian violet** – prohibited from use in food or feed of food-producing animal species
- **Indexed drugs** – some exceptions for minor-use species
- **Phenylbutazone** – in female dairy cattle (20 months of age or older)
- **Sulfonamide-class antibiotics** – in lactating dairy cattle – approved uses are allowed for sulfadimethoxine, sulfabromomethazine, and sulfaethoxypyridazine

and the veterinarian, that proper animal identification and documentation be maintained, and that the veterinarian makes every effort to determine an extended withdrawal time for this usage (e.g., consult with a resource such as the Food Animal Residue Avoidance Databank, FARAD), which the producer must adhere to. The regulation prohibits extralabel use for routine production purposes, routine disease prevention, or as feed additives.

Pharmacokinetics and Residues

Pharmacokinetics is the science of quantitating the change in drug concentration in the body over time as a function of the administered dose. Although this discipline has been covered in Chapters 2 and 3 of this text and elsewhere (Riviere, 1992b, 1999, 2011; Baynes and Riviere, 2014), it is important to review some principles here since it serves as the basis for understanding withdrawal times.

How a drug or combination of drugs behaves in the body after administration not only is important from a therapeutic point of view but is of paramount importance to the producer and veterinarian in order to prevent residues in the edible tissues after the disease process has been resolved and the animal is slaughtered. For therapeutic usefulness and drug residue determinations, a known amount of drug is administered to a healthy animal. Serum concentration data are collected and mathematical models are created so that the overall disposition of the drug in the body can be evaluated in relation to absorption, distribution, metabolism, and elimination. Parameters for these models are estimated by fitting regression lines to the observed serum concentration versus time profiles, an example of which is shown in Chapter 3, Figure 3.15.

The slopes of the three lines shown in Figure 3.15, when plotted on a semilogarithmic plot, represent distribution (λ_1), short-term elimination (λ_2), and long-term elimination (λ_3) from the body. The λ_1 (or α) and λ_2 (or β) phases of the serum concentration versus time profile are the only phases that are usually present when serum concentrations are monitored over a short period of time after dosing and are typically used to predict therapeutic drug concentrations. When serum concentrations are monitored for longer periods of time after drug administration using more sensitive analytical assay methods, however, the λ_3 (or γ) phase of elimination appears for certain compounds. This can be present for several days or several months after the last administered dose depending on the drug's physicochemical properties, the amount of drug administered, and the species in which it was administered. This λ_3 phase reflects drug disposition in the so-called "deep compartments." Alternatively, for prolonged-action depot preparations (e.g., benzathine penicillin), this terminal phase may actually reflect the rate-limiting absorption phase ("flip–flop" phase). For purposes of determining withdrawal times of drugs that may be used in food-producing animals, we will focus our discussion on the terminal phase of drug elimination to determine the half-life ($t_{1/2}$) of the drug in the body, since this is the measurement that is relevant in determining drug withdrawal times.

In the actual research studies conducted to determine a withdrawal time, it is the half-life of drug in the specific tissue that is of paramount importance. This information is not available to the veterinarian. Additionally, tissue pharmacokinetics are exceedingly complex, and a discussion here of terminal half-lives will be sufficient to illustrate the concepts involved. For more in-depth information on the clinical application of pharmacokinetics and how pharmacokinetic parameters can affect clinical parameters, readers should consult Chapters 2 and 3 of this textbook.

The half-life of the drug or chemical in the body is the primary biological measurement used to determine withdrawal times of drugs and chemicals in food-producing animals; however, this parameter can be influenced by many biological factors (Baynes and Riviere, 2014; Baynes et al., 2015). The $t_{1/2}$ of a drug by definition is the time is takes for 50% of the drug in the animal to be eliminated from the body and is based on the terminal slope of the elimination curve used to determine the withdrawal time of a drug. The $t_{1/2}$ is calculated using the equation

$$t_{1/2} = \ln 2/\text{slope or } t_{1/2} = 0.693/\text{slope}$$

If the concentration of a drug in the muscle of a food animal after dosing is 100 parts per million (ppm), then the time it takes for the concentration in the muscle to decrease to 50 ppm would be the biological half-life of the drug in the muscle. Extrapolated out, the amount of drug in the muscle after 10 half-lives would be 0.1 ppm, or, put in other terms, 99.9% of the drug would have been eliminated from the muscle after 10 half-lives. If the dose is doubled and the beginning concentration in the muscle is now 200 ppm, only 1 additional half-life would be required to reach the 0.1 ppm concentration. On the other hand, if the half-life of the drug in the muscle is doubled, perhaps due to a disease state, then the elimination half-life would also double, thereby increasing the risk of violative drug residues in the edible tissues of that animal. These two scenarios, if properly understood, are simple tools to reduce violative residues when drugs are used in an extralabel fashion or according to label in severely diseased animals.

As stated above, the elimination half-life can be influenced by many biological factors. The half-life of a drug or chemical in the body is influenced by how well it distributes in the body and how quickly it is eliminated from the body. The physicochemical properties of a drug can influence its disposition in the body – in particular, how well it distributes into certain tissues, whether or not it penetrates intracellularly, or whether it permeates the blood–brain barrier. The volume of distribution (V_d) is the quantitative estimate of the extent of the distribution of the drug in the body and can therefore directly influence the $t_{1/2}$ of the drug. It is a proportionality constant relating the concentration of drug in the serum to the total amount of drug in the body. For an intravenous injection of a drug, the equation for calculating V_d is

$$V_d = \text{amount of drug in the body/}\\ \text{serum drug concentration}$$

It is important to point out that the V_d, typically reported in l/kg, does not actually refer to any specific physiological space or body area; rather, it gives a good indication of how well a drug in general distributes throughout the body. A drug that has a large V_d typically has good tissue distribution throughout the body (e.g., tetracyclines), while a drug with a small V_d has less penetration into the body tissues as whole, perhaps being confined to the extracellular spaces due to one or more of its physicochemical properties (not lipid soluble, fixed charge). While V_d may give an indication of the overall distribution of a drug, some drugs may not be uniformly distributed throughout the body. In this case, a drug may seek specific cells or organs or be bound to tissue macromolecules, resulting in a large V_d measurement and yet a relatively poor overall distribution in a majority of the body's tissues. Some drugs may have prolonged withdrawal times due to a large V_d.

In addition to V_d, the clearance (Cl) of the drug also plays an important part in determining the withdrawal time of the drug. Clearance quantitates the efficiency of the elimination processes and is defined as the rate of drug elimination from the body relative to the concentration of drug in the serum by the equation

$$Cl = \text{rate of elimination/serum drug concentration}$$

Drugs that have a slow rate of elimination from the body will tend to have protracted half-lives, while those that are eliminated quickly will have shorter half-lives.

The $t_{1/2}$ is dependent on two functions: V_d and Cl. By combining terms, an equation can be derived that reflects the influence of V_d and Cl on the $t_{1/2}$ of a drug:

$$t_{1/2} = \ln 2V_d/Cl \text{ or } t_{1/2} = 0.693V_d/Cl$$

Several physiological events can occur to change V_d or Cl and can therefore influence the $t_{1/2}$ of the drug in the body. For example, if renal function is impaired, the drug's clearance may be reduced and the $t_{1/2}$ prolonged by several hours or several days, in turn prolonging the withdrawal time of the drug. If the animal's fluid balance changes, the V_d may change accordingly. Factors such as the age, nutritional status, percentage of body fat, species, presence of other drugs, and extent of protein binding can all have a significant role in determining the V_d and Cl and hence the $t_{1/2}$ of any drug introduced into the body. For more information on the pharmacokinetics, readers are encouraged to consult Chapters 2 and 3.

Recent work has used physiologically based pharmacokinetic modeling (similar to Figure 3.18) to develop models that incorporate tissue compartment measurements into their structure (Craigmill, 2003; Buur et al., 2005, 2006; Leavens et al., 2014; Lin et al., 2016). These models also allow direct incorporation of statistical estimates of population variability in all processes impacting on residue depletion to be included in the modeling. Their downside is that significant data are required for their solution.

The pharmacokinetic behavior and efficacy of the drug or chemical used to treat a disease process are of major concern early on in the successful management of herd health in food animals. For residue control in food-animal species, the primary purpose of knowing the pharmacokinetic behavior of the drug (i.e., the terminal elimination half-life) is to determine the withdrawal time to avoid residue accumulation in those tissues consumed by humans. A knowledge of what physiological processes affect the half-life is thus essential to determine when a withdrawal time might need to be modified due to disease-induced prolongation of the withdrawal time.

Theoretically, if a tissue tolerance and the dose of drug were known, pharmacokinetic techniques could be used to calculate an individual withdrawal time. For an oral drug, this requires knowing the fraction of the dose administered which is absorbed into the body (e.g., bioavailability). This amount, divided by the V_d, is the initial concentration of drug in the body (C^0). If one were to assume that the loss of drug from the body were only dependent upon the terminal withdrawal time, then adjusting Equation 3.10 by solving for T as the withdrawal time, and substituting K as 1.44 $t_{1/2}$, the following relationship can be derived as

$$\text{withdrawal time} = 1.44 \ln\left(C^0/\text{tolerance}\right)\left(t_{1/2}\right).$$

Of course, this is an oversimplification. In reality, this equation would work if C^0 were the concentration of drug in the target tissue at the end of drug administration, as this amount is dependent upon the λ_2-phase elimination processes. Complex pharmacokinetic models can be used to calculate this number. Then the above equation would be valid. Officially established withdrawal times must take into account all interanimal variability, and thus statistical processing of these data establishes the withdrawal time for the worst-case scenario.

The above equation is useful to gain a perspective on what the withdrawal time is relative to the terminal half-life. Assume that for most antibiotics a "therapeutic" concentration is 10 μg/ml and the tissue tolerance is 0.01 ppm (0.01 μg/ml). One also must assume homogeneous distribution of the drug throughout the body. Thus, withdrawal time equals 1.44 [ln (10/0.01)] $t_{1/2}$, or 9.94 $t_{1/2}$. A withdrawal time for this drug would be equal to 10 half-lives. If the drug has a short half-life (e.g., penicillin), the withdrawal time is short. However, if the drug has a prolonged tissue half-life (e.g., an aminoglycoside), the withdrawal time could exceed a year in the target tissue. Similarly, a drug with a very low tissue tolerance has a longer withdrawal time because ln (C^0/tolerance) is now greater. If a drug is metabolized, the metabolite may determine the withdrawal time ("marker residue") since its half-life is rate limiting.

This "rule of 10" can be derived by assuming that 10 half-lives are required to eliminate 99.9% of an administered dose, as discussed earlier in this section. An examination of half-lives and withdrawal times for a number of approved pharmaceutics confirms this relation as being very conservative relative to human food safety end points (Gehring et al., 2004). In fact, these so-called "half-life multipliers" of 4–5 were often sufficient since the target tolerance for drugs with minimal adverse effects was not at very low concentrations reflective of complete drug elimination. Using a divisor of 5 could actually be considered even more conservative since the additional time added to the withdrawal time would be longer.

This relationship is important to consider when one administers an increased dose of drug. If the dose is doubled, withdrawal time should just be increased by a single half-life. In the above example, the calculation would 1.44 ln (20/0.01), or 10.94 half-lives, which confirms this concept. However, if a disease process changed the half-life by either increasing volume of distribution or decreasing clearance (e.g., kidney disease) causing the half-life to double, withdrawal time should be doubled. This phenomenon supports the observation that *seriously ill animals with altered pharmacokinetics deserve increased attention to ensure complete drug withdrawal.* It is also important to note that withdrawal time is determined in healthy animals, and thus serious disease conditions may cause residues even when the approved dose and official withdrawal time are used. *It is critical for a veterinarian to have a conceptual understanding of this relationship between withdrawal time and half-life before doses are modified in food-producing animals.* When such a withdrawal time is calculated, the animal should be checked with the appropriate rapid screening test.

A clear example of this is seen with the antiinflammatory drug flunixin where prolonged withdrawal times are needed for dosing if severe inflammation is present (Wu et al., 2013; Leavens et al., 2014; Kissel et al., 2015; Smith et al., 2015). The cause of this seems to be both reduced clearance and altered metabolic profile seen with severe inflammatory diseases such as clinical mastitis or modeled using endotoxin injection. The withdrawal time is established in healthy animals yet the drug is labeled to be used in diseased animals. Similar changes in a drug's metabolism would also be expected for drugs such as sulfamethazine, enrofloxacin, and ceftiofur. This change in clearance and metabolic pattern also changes the marker residue ratio and its relationship to total drug, which brings into question the true validity of using this fixed ratio to determine regulatory tolerances (Lin et al., 2016).

For lactating dairy cows and goats, the identical principles apply to determining the milk discard times. The milk discard or withholding time is the time after drug administration when the milk cannot be used for human consumption. This is determined by administering the drug and collecting and analyzing milk until drug concentrations are below the milk tolerance established for that drug. Like withdrawal times, the discard time is product and species dependent. In this case, it is based on the half-life of the drug in the milk. If one knows the concentration of the drug in the milk at the end of drug administration, the milk half-life, and the milk tolerance, the above equation can be used to precisely calculate withdrawal. This has been particularly useful when valuable dairy cows have been accidentally exposed to pesticides (e.g., heptachlor) and pharmacokinetic data were used to determine milk discard times since approved withdrawal times do not exist. In this case, the relevant parameter is the half-life of drug in milk. All of the principles discussed above relative to meat withdrawal apply. The half-life in milk is a function of how the drug is excreted into the milk after systemic administration (or oral or interuterine) or is retained in the udder after intramammary infusion. For example, basic drugs such as erythromycin have longer discard times than acidic drugs such as penicillin because the former tend to distribute more readily into milk due to the pH partitioning phenomenon. Similarly, lipophilic drugs will tend to have longer milk discard times. Discard times are different for these different routes of administration. One must be sure that a drug used as dry cow therapy is not inadvertently administered to a lactating cow, because the residue concerns are different since most dry cow formulations are long-acting preparations.

Drugs Prohibited from Extralabel Use

Certain drugs are prohibited from extralabel use in food animals under AMDUCA (Table 61.1). This is a constantly changing list and thus up-to-date sources should always be consulted. The FDA may prohibit the extralabel use of an approved new animal or human drug or class of drugs in food animals if FDA determines that the extralabel use of the drug or class of drugs presents a risk to the public health, or an acceptable analytical method needs to be established but such method has not been established. A prohibition may be a general ban on the extralabel use of the drug or class of drugs or may be limited to a specific species, indication, dosage form, route of administration, or combination of factors. Finally, extralabel use is prohibited for drugs added to animal feeds.

Residue Prevention

Although public awareness of the drug residue problem in food is high and several governmental agencies spend large amounts of time attempting to control this problem, residues in animal tissues are still an important concern today. The responsibility for residue control and prevention cannot lie solely within a governmental agency; rather, the responsibility must be shared by the government, producers, veterinarians, teachers and academicians, marketing associations, and other interested parties, who must strive for both healthy and efficiently grown animals as well as a safe food supply. Several approaches can be taken to achieve this goal.

The first step in residue prevention is to make individuals and organizations aware of the problem through education. Education of laypersons can be accomplished through a variety of mechanisms: available open lay and veterinary medical literature, computer databases, consultations with veterinary medical personnel, or the efforts of national organizations. A number of national producer organizations have firm initiatives in place to prevent harmful residues in food-producing animals, including dairy (Adams, 1993), beef (Wilkes, 1993), pork (Lautner, 1993), and veal (Wilson and Dietrich, 1993) organizations. Awareness has also been raised concerning some species of companion animals (Macomber, 1993; Kay, 1993).

Failure to observe the correct withdrawal time of a drug was the leading cause of tissue residue violations in two studies (Van Dresser and Wilckie, 1989; Bevill, 1984). Once the importance of residue control in the US food supply is made clear and the importance of observing the correct legal withdrawal times for the drugs used in food-producing animals is understood, the incidence of tissue residue violations will (theoretically) decrease dramatically. Many have reported on other possible ways to reduce or prevent residues from occurring in food animals (Gehring et al., 2006; Riviere, 1991; Marteniuk et al., 1988; Sundlof, 1989; Kindred and Hubbert, 1993; Mercer, 1990). Rapid screening test technology has advanced significantly and has been used to detect low levels of residue contamination in slaughtered animals in a quick manner. As these tests become more sensitive and more widely used, animals with residue contamination can be isolated and removed before reaching the end consumer, further decreasing the residue problem.

Several rapid screening tests are available. They are powerful tools for the veterinarian using a drug in an extralabel manner or in a seriously diseased animal. Once the veterinarian establishes a putative withdrawal time using the principles discussed above, the animal should be tested with the appropriate rapid screening assay to ensure that the prediction is accurate. If a residue is detected, a prolonged withdrawal time should be recommended until a negative screening value is observed. If this practice is followed, the veterinarian will have done everything possible to ensure a residue-free product.

FARAD is a USDA-supported computerized databank of scientific and regulatory information, established in 1982 and reauthorized by the US Congress in 1998, that can assist the veterinarian, producer, or other individuals in making rational choices in preventing drug and pesticide residues in food animals. It is a collaboration between Kansas State University, North Carolina State University, University of California at Davis, and University of Florida at Gainesville. FARAD contains information on: veterinary drug registration information; current label information; foreign registration and safety data; tolerances for drugs and pesticides for tissues, eggs, and milk; withdrawal information; physicochemical properties; pharmacokinetic and toxicokinetic information; residue test information; bibliographic citations; and other information useful in preventing drug residues in food animals. The database is regularly updated to provide users with the most current information available. FARAD is easily accessed by voice telephone (888-USFARAD), the internet (www.farad.org), and e-mail at three regional access centers (Kansas State University, North Carolina State University, and University of California Davis). By contacting an access center, users can obtain any of the current information listed above. FARAD services are free to clientele. FARAD also publishes periodic updates on extralabel drug withdrawal time estimates and other issues as a regular feature in the *Journal of the American Veterinary Medical Association* (FARAD DIGESTS). The program's website (www.farad.org) should be consulted for orientation to its services and current access information. More information on FARAD is available elsewhere (Riviere et al., 1986; Payne et al., 1999, Baynes and Riviere, 2014).

Other sources of drug information pertaining to residues in food animals are also available. The FARAD pharmacokinetic data have been published in book form (Craigmill et al., 2006). The Food and Agriculture Organization (FAO) and World Health Association (WHO) Joint Expert Committee on Food Additives (JECFA) has evaluated several drugs and has published monographs that list toxicity, metabolism, acceptable daily intakes, maximum residue levels permitted for different tissues, and biological fate of drugs in food-producing animals.

The prevention of harmful residues in the edible tissues of our food-producing animals is the responsibility of many producers, veterinarians, professional and layperson associations, and governmental agencies. All of these groups must continue to strive to regulate and utilize the drugs used to prevent or cure animal diseases in a responsible manner in order to prevent the accumulation of harmful amounts of residues in the food supply.

  efficacy, 1182
  safety/toxicity, 1182–1183
amitriptyline, 176, 430
amnestic effects of inhaled anesthetics, 223
amoxicillin–clavulanate, 837
amoxicillin, in aquatic animals, 1386
amphibian, drugs for, 1396
amphotericin B, 990–993
  adverse effects, 991, 993
  clinical use, 991
  combination therapy with, 990
  dosing protocols for, 992t
  formulations of, 990
  mechanism of action, 990
  for ocular infections, 1328
  pharmacokinetics, 991
  spectrum of activity, 990–991
  structure of, 990f
amprolium, 1144, 1144f
anabolic steroids, 684–685
anabolic steroids, use of, in racing horses, 1445–1446
ANADAs. *see* Abbreviated New Animal Drug Applications
analgesia
  barbiturates, 252
  butyrophenone and, 329
  dissociative anesthetics, 262
  etomidate, 265
  flumazenil and, 337
  guaifenesin and, 355
  meperidine, 312–313
  morphine, 312–313
  neurosteroid anesthetics, 268
  nitrous oxide, 224
  opioids, 281, 285–286
  phenothiazines, 326
  xenon, 224
anandamide, 177
anemia, sulfonamides and, 806
anesthesia, 180, 183
  anesthetic protocol and drug, selection of, 185, 186t
  classification of, 183–185, 183t
  depth of, 189
  general, 184–185
  immediate postanesthetic period, drugs in, 188–189
  local and regional, 183–184, 183t
  perianesthetic period, drugs in, 188, 188t
  preanesthetic medication, 186
    α_2-adrenergic drugs, 187
    dissociative drugs, 187
    drug classes for, 186t
    drug combinations, 187
    goals for, 186t
    hypnotic-sedatives, 187
    opioids, 187
    parasympatholytic (anticholinergic) drugs, 187–188
    tranquilizer-sedatives, 186–187
  response to, evaluation of, 189–191, 190f
  route of administration, 183t
anesthesiology
  anesthetic use, 181t
    immobility, 183
    perception of noxious stimulus, 181–183
  definition of, 180
anesthetic recovery period, 188–189, 189t
anesthetics
  and acid-base metabolism, 588–589
  for food animals, 1369–1370
  inhalation (*see* inhalation anesthetics)
  injectable (*see* injectable anesthetics)
  local (*see* local anesthetics)
anesthetist, role of, 180
angiotensin converting enzyme (ACE), 65, 66, 84
angiotensin-converting enzyme inhibitors (ACEIs), 558, 615–617
  absorption and elimination of, 616
  adverse effects, 518, 616–617
  chemistry/formulations of, 615
  in chronic kidney disease, 520
  drug interactions, 520, 616–617
  efficacy, 518–520
  mechanisms and sites of action, 517–518, 615–616
  therapeutic uses, 617
  toxicity, 616–617
  in use, 520
angiotensin I, 558
angiotensin II, 558
  effects on renal functions, 597–599
angiotensin receptor antagonists, 615–617
angiotensin receptor blockers (ARBs), 615, 616–617
angular limb deformities in foals, tetracyclines for, 870
Animal and Plant Health Inspection Service, 1408
Animal Drug Availability Act (ADAA), 1410–1411
Animal Drug User Fee Act (ADUFA), 1361
Animal Health Institute (AHI) website, 1412
Animal Medicinal Drug Use Clarification Act (AMDUCA), 41, 882, 1185, 1346–1348, 1358, 1373, 1395, 1410, 1472
anion gap (AG), 571–572
Anoplocephala perfoliata infections, 1081
ANP. *see* atrial natriuretic peptide
antacids, 1255–1256

  adverse effects, 1255
  dose recommendations, 1255–1256
  formulations, 1255
anterior uveitis, 1232
anthelmintics, 1369
anthraquinone, 1270
antiandrogens, 678t
antiarrhythmic agents
  amiodarone, 549–550
  atenolol, 546
  beta-blockers, 545
  calcium channel blocking drugs, 545
  classification, 542–543, 542t–543t
  digoxin, 544–545
  esmolol, 546
  heart rhythmicity
    arrhythmogenic mechanism classification, 540–542, 540f–541f
    cardiac cell electrophysiologic properties, 537–540, 538f–539f
  isoproterenol, 544
  lidocaine, 548–549
  mexiletine, 549
  procainamide, 547
  propantheline bromide, 543–544
  quinidine, 547–548
  sotalol, 546, 550
antibacterial agents, for ocular infections, 1326–1328
antibiotic-impregnated polymethylmethacrylate (AIPMMA), 881
antibiotic-responsive enteropathy, 1265
antibiotic use, in food animals, 1361–1365, 1362t–1363t
anticestodal drugs, 1081
  bunamidine, 1081–1082, 1082f
  epsiprantel, 1085, 1085f
  niclosamide, 1082, 1082f
  praziquantel, 1082–1085, 1082f
anticholinergics, 188, 1310
  adverse effects, 1310
  for diarrhea, 1263–1264, 1264t
  in horses, 1310
  for inflammatory bowel diseases, 1268
anticoagulants
  for blood and blood component transfusions, 629
  natural, in hemostasis, 628
  new drugs, 636t
anticoccidials, 1365, 1366t
anticonvulsant drugs
  bromide, 409–411
  clonazepam, 404
  clorazepate, 404–405
  diazepam, 402–404
  felbamate, 405
  gabapentin, 405–406
  imepitoin, 401–402
  levetiracetam, 407–408
  midazolam, 404
  phenobarbital, 395–399
  phenytoin, 400–401
  pregabalin, 406–407
  primidone, 399–400
  used in veterinary medicine, 396t
  valproic acid, 401
  zonisamide, 408–409
antidiuretic hormone (ADH), 558, 600, 665–667
  absorption, metabolism, and excretion of, 665
  for diagnosis of diabetes insipidus, 666
  mechanism of action, 665, 666t
  preparation of, 665
  stimulus for release, 665
  structure of, 665
  therapeutic uses, 666–667
  toxicity of, 667
antiemetic drugs, 1245–1250, 1246t
  antihistamines, 1246
  antimuscarinic drugs, 1245–1246
  cannabinoids, 1247–1248
  glucocorticoids, 1247
  metoclopramide, 1247
  mirtazapine, 1249–1250
  NK-1 receptor antagonists, 1248–1249
  phenothiazine tranquilizers, 1245
  serotonin antagonists, 1247
antiepileptic potassium bromide, 702
antifibrinolytic drugs, 641–642
antifungal drugs, 988
  amphotericin B, 990–993
  azole, 993–1006
  drug–drug interactions, 995t
  flucytosine, 1008
  griseofulvin, 988–990
  lufenuron, 1007–1008
  for ocular infections, 1328
  sites of action, 989f
  sodium or potassium iodide, 1008
  terbinafine, 1006–1007
  topical
    clotrimazole, 1009
    enilconazole, 1008–1009
    mefenoxam, 1009–1010
    miconazole, 1009
    natamycin, 1010
    nystatin, 1010
antihistamines, 1246, 1246t
  chemistry, 456–457
  development, 456
  H_1 receptor antagonists, 456, 457t
  H_2 receptor antagonists, 460
  pharmacological effects, 457
  side effects and interactions, 459–460
  therapeutic uses, 457–459
  therapeutic uses of, 459
antiinflammatories use, in food animal, 1365–1368, 1366t
antiinflammatory and antiallergic therapy, glucocorticoids, 745
antimetabolites, 1206–1210
  cytosine arabinoside, 1207–1208, 1208f
  5-fluorouracil, 1209–1210, 1209f
  gemcitabine, 1208–1209, 1209f
  methotrexate, 1206–1207, 1207f, 1208f
antimicrobials, for diarrhea, 1264t, 1265–1267
antimicrobial susceptibility testing (AST), 1378, 1379
antimicrotubule agents, 1210–1211
  vinca alkaloids, 1210–1211, 1210f
antimuscarinic drugs, 1245–1246, 1246t
antinematodal drugs, 1035
  benzimidazoles and pro-benzimidazoles, 1035–1054
    administration routes, 1050
    anthelmintic spectrum, 1047–1049
    chemistry of, 1035–1037, 1036f
    disposition kinetics and efficacy of, 1050–1053
    drug transfer into target parasites, 1046–1047
    formulations of, 1050, 1053
    pharmacodynamics, 1037
    pharmacokinetics, 1037–1046
    structures of, 1035, 1036f
    withdrawal times, safety, and toxicity, 1053–1054
  drug combinations, use of, 1067–1069
  heartworm adulticides, 1064
  heterocyclic compounds, 1062–1064

antinematodal drugs (*Continued*)
    diethylcarbamazine, 1063–1064, 1063f
    phenothizaine, 1062
    piperazine, 1062–1063, 1063f
  imidazothiazoles, 1054–1058
  novel drugs, 1069–1072
  organophosphate compounds, 1061–1062
  resistance to, 1065–1067
  tetrahydropyrimidines, 1058–1061
antinuclear antibodies (ANA), 717
antiplatelet drugs, 638–640
  aspirin, 638–639
  clopidogrel, 639–640
  ticlopidine, 640
antiprostaglandins, 178
antiprotozoan drugs, 1128, 1129t–1131t
  alkaloids, 1146
    halofuginone, 1146, 1146f
  aminoglycosides, 1138
    paromomycin, 1138–1139, 1138f
  4-aminoquinolines, 1156
    chloroquine, 1156
  arsenicals, 1137
  azalides, 1156
    azithromycin, 1156
  benzimidazoles, 1137, 1137f
    albendazole, 1137–1138
    febantel, 1138
    fenbendazole, 1138
  for coccidiosis, 1132t–1133t
  diamidine derivatives, 1157, 1157f
    amicarbalide, 1158
    diminazene diaceturate, 1157–1158
    imidocarb diproprionate, 1158–1159
    pentamidine isethionate, 1158
    phenamidine isethionate, 1158
  dihydrofolate reductase/thymidylate synthase inhibitors, 1152, 1153f
    ormetoprim, 1153f, 1154
    pyrimethamine, 1153f, 1154–1155
    trimethoprim, 1152–1154, 1153f
  guanidine derivatives, 1143
    robenidine, 1143–1144, 1143f
  hydroxyquinolones and naphthoquinones, 1141, 1141f
    atovaquone, 1141f, 1142–1143
    buparvaquone, 1141f, 1143
    decoquinate, 1141–1142, 1141f
    parvaquone, 1141f, 1143
  lincosamides, 1155, 1155f
    clindamycin, 1155–1156, 1155f
  nicarbazin, 1145–1146, 1145f
  nitrobenzamides, 1144–1145, 1145f
    aklomide, 1145, 1145f
    dinitolmide, 1145, 1145f
  nitrofurans, 1139
    nifurtimox, 1139–1140, 1140f
  nitroimidazoles, 1128, 1134f
    benznidazole, 1135
    metronidazole, 1128, 1131, 1133–1134
    ronidazole, 1135
    secnidazole, 1135
    tinidazole, 1134–1135
  nitrothiazole derivatives, 1159
    nitazoxanide, 1159
  pentavalent antimonials, 1135–1136, 1136f
    meglumine antimonate, 1136
    sodium stibogluconate, 1136, 1136f
  polyether ionophores, 1146–1147, 1147f
    lasalocid, 1147–1148, 1147f
    maduramicin, 1147f, 1148

tyrosine kinase inhibitors, 1214–1215
  masitinib, 1215
  toceranib, 1214–1215, 1214f

U

UDP-glucuronyl transferase (UGT) enzymes, 1338
ulceration, gastrointestinal, 1254–1262
ulcerative colitis, in dogs, 1266
unfractionated heparin (UFH), 629
unitary theory of narcosis, 185
United States Department of Agriculture (USDA), 1350, 1470, 1471
United States Equestrian Federation (USEF), 1440, 1444
United States Pharmacopeia (USP), 4, 5, 1431, 1435, 1451
up-regulation, 76
ureidopenicillins, 836
urethane, 271f
  carcinogenicity, 271
  chemistry, 271
  dose, 271
  drug availability, 271
  history, 270
  mechanism of action, 271
  metabolism, 271
  physiological effects, 271
  regulatory information, 271
urokinase, 641
ursodeoxycholic acid, 1271
US Controlled Substances Act, 1970, 247
US Department of Agriculture, 1408
USEF. *see* United States Equestrian Federation
uterine contractions, prostaglandins analogs and, 681
uterine infections, prostaglandins analogs for, 682
uterus, oxytocin function in, 680

V

valacyclovir, 1010–1012
  adverse effects, 1012
  clinical use, 1011–1012
  pharmacokinetics, 1011
  spectrum of activity, 1011
valganciclovir, 1013
valproic acid, 401
vancomycin, 936–937, 1265
  administration guidelines, 937

  adverse effects, 937
  clinical use, 937
vapor pressure, of anesthetic, 218
vasopressin, 614–615
  effects of drugs and electrolytes, 559f
Vasostrict, 666
vecuronium, 197, 200–201
  characteristics of, 199t
ventricular tachycardia, antiarrhythmic agents for, 546–550
vesicular glutamate transporters (VGLUTs), 172
vesicular monoamine transporter (VMAT), 175
The Veterinarian's Vade Mecum, 5
veterinary biologics, 1408
Veterinary Co-operative Oncology Group Common Terminology Criteria for Adverse Events (VCOG-CTCAE), 1191–1192
Veterinary Drug Information Monographs, 1466
veterinary feed additives, 1461–1463, 1463f
veterinary feed directive (VFD), 1349, 1411, 1420, 1430, 1461
Veterinary International Committee on Harmonization (VICH), 1365
Veterinary Material Medica and Therapeutics, 5
Veterinary Medical Dictionary for Drug Regulatory Authorities (VeDDRA), 1453
veterinary pharmacology, 4–7
Veterinary Services, 1408
Veterinary Susceptibility Testing Subcommittee (VAST) of Clinical and Laboratory Standards Institute (CLSI), 6
Vetoryl, 753
Vetstarch, 582t
VICH (International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products), 1425
vidarabine, 1014
vinblastine (VBL), 1210–1211, 1210f
vinca alkaloids, 1210–1211, 1210f
  extravasation, 1199
vincristine (VCR), 1210–1211, 1210f
Vinstrol-V, 678t
virginiamycin, 935–936
Virus Serum Toxin Act, 1408
visceral targets, 152f
vitamin K_1, 637–638
vitamin K_2, 637
vitamin K_3, 637
vitreous humor (VH), 1321
volatage-gated Na^+ channels, 66
volatile inhalation anesthetics
  effects on arterial oxygen tension (P_ao_2), 224, 225f
  myocardial contractility and, 226
vomiting center, 178
vomiting, neurotransmitters involved in, 1245, 1246t. *see also* antiemetic drugs
von Willebrand factor (vWF), 626
voriconazole, 993t, 1003–1005
  adverse effects, 1005
  clinical use, 1005
  pharmacokinetics, 1003–1005
  structure of, 1003, 1004f

W

warfarin, 632–638
  adverse effects of, 635
  agents to reverse, 637–638
  clinical use, administration, and monitoring, 634–635
  mechanism of action, 633
  pharmacological properties of, 633t, 634
  precautions in using, 635
  structure of, 633f
  thrombin inhibitors, 635–636
  vitamin-K cycle and, 634f
waterborne treatments, 1377–1378
water, sodium, and chloride, 558–565
  disorders of balance, 561–565
  homeostasis, 558–559, 559f
  renal regulation of excretion of, 559–561, 560f
wet/dry granulation, 105–106
white petrolatum, 1271
Winstrol-V, 685
withdrawal intervals, estimation of
  allometric scaling, 1353–1354
  comparative pharmacokinetics, 1351–1353
  species grouping, 1354
  in vitro and molecular studies, 1354–1355
withdrawal time, 1469, 1470, 1471, 1475
  definition of, 1443
  factors affecting, 1443
Wolff–Chaikoff effect, 693
World Health Organization (WHO), 1426, 1449, 1476

X

xanthines. *see* methylxanthines
xenobiotics, 1400
xenon
  analgesic actions of, 224
  solubility of, 218t
xylazine hydrochloride, 343–346, 345f
xylazine, in preanesthetic period, 187
xylitol, 96
xylometazoline, 1315

Y

yohimbine, 144, 350–351, 351f, 351t

Z

zafirlukast, 1314
zidovudine, 1014–1015
  adverse effects, 1015
  clinical use, 1015
  pharmacokinetics, 1014–1015
zileuton, 1314
zilpaterol, 1306, 1368
Zolatel®, 259
zolazepam, 262, 263
  chemical name, 335
  molecular formula, 335
  regulatory information, 335
zolpidem, 427–428
zonisamide, 408–409
  adverse effects, 406
  clinical use, 409
  pharmacokinetics, 408–409
zoological pharmacology, 1395
  allometry in, 1400–1401
  invertebrates, 1395–1396
  vertebrates
    avian, 1397
    mammalian, 1397–1400
    reptile and amphibian, 1396
